March 21, 2019

Abstract

We present a new solution framework to solve the generalized trust region subproblem (GTRS) of minimizing a quadratic objective over a quadratic constraint. More specifically, we derive a convex quadratic reformulation (CQR) via minimizing a linear objective over two convex quadratic constraints for the GTRS. We show that an optimal solution of the GTRS can be recovered from an optimal solution of the CQR. We further prove that this CQR is equivalent to minimizing the maximum of the two convex quadratic functions derived from the CQR for the case under our investigation. Although the latter minimax problem is nonsmooth, it is well-structured and convex. We thus develop two steepest descent algorithms corresponding to two different line search rules. We prove for both algorithms their global sublinear convergence rates. We also obtain a local linear convergence rate of the first algorithm by estimating the Kurdyka-Łojasiewicz exponent at any optimal solution under mild conditions. We finally demonstrate the efficiency of our algorithms in our numerical experiments.

1 Introduction

We consider the following generalized trust region subproblem (GTRS),

$$\begin{aligned} \text{(P)} \quad & \min \quad f_1(x) := \frac{1}{2}x^\top Q_1 x + b_1^\top x \\ & \text{s.t.} \quad f_2(x) := \frac{1}{2}x^\top Q_2 x + b_2^\top x + c \leq 0, \end{aligned}$$

where Q_1 and Q_2 are $n \times n$ symmetric matrices (not necessary positive semidefinite), $b_1, b_2 \in \mathbb{R}^n$ and $c \in \mathbb{R}$.

Problem (P) is known as the generalized trust region subproblem (GTRS) [44, 40]. When Q_2 is an identity matrix I and $b_2 = 0$, $c = -1/2$, problem (P) reduces to the classical trust region subproblem (TRS). The TRS first arose in the trust region method for nonlinear optimization [14, 50], and has found many applications including robust optimization [8] and the least squares problems [51]. As a generalization, the GTRS also admits its own applications such as time of arrival problems [24] and subproblems of consensus ADMM in signal processing [27]. Over the past two decades, numerous solution methods have been developed for TRS (see [37, 35, 49, 41, 23, 20, 4] and references therein).

Various methods have been developed for solving the GTRS under various assumptions (see [36, 44, 10, 45, 15, 40, 5] and references therein). Although it appears to be nonconvex, the GTRS enjoys hidden convexity. The GTRS can be solved via a semidefinite programming (SDP) reformulation, due to the celebrated S-lemma [39], which was first established in [48]. However, suffering from relatively large computational complexity, the SDP algorithm is not practical for large-scale applications. To overcome

*School of Data Science, Fudan University, Shanghai, China, rjjiang@fudan.edu.cn

†School of Data Science, City University of Hong Kong, Hong Kong, dli226@cityu.edu.hk

this difficulty, several recent papers [28, 13, 25] demonstrated that the TRS admits a second order cone programming (SOCP) reformulation. Ben-Tal and den Hertog [7] further showed an SOCP reformulation for the GTRS under a simultaneous diagonalization (SD) condition of the quadratic forms. Jiang et al. [29] derived an SOCP reformulation for the GTRS when the problem has a finite optimal value and further derived a closed form solution when the SD condition fails. On the other hand, there is rich literature on iterative algorithms to solve the GTRS directly under mild conditions, for example, [36, 44, 40, 42]. Pong and Wolkowicz proposed an efficient algorithm based on minimum generalized eigenvalue of a parameterized matrix pencil for the GTRS, which extended the results in [17] and [41] for the TRS. Salahi and Taati [42] also derived a diagonalization-based algorithm under the SD condition of the quadratic forms. Recently, Adachi and Nakatsukasa [5] also developed a novel eigenvalue-based algorithm to solve the GTRS.

Our main contribution in this paper is to propose a novel convex quadratic reformulation (CQR) for the GTRS that is simpler than [7, 29] and further a minimax problem reformulation and develop an efficient algorithm to solve the minimax problem reformulation. Numerical results demonstrate that our method outperforms all the existing methods in the literature for sparse problem instances. We acknowledge that our CQR was inspired by the following CQR in Flippo and Janson [16] for the TRS,

$$\min_x \left\{ \frac{1}{2} x^\top (Q_1 - \lambda_{\min}(Q_1)I)x + b_1^\top x + \frac{1}{2} \lambda_{\min}(Q_1) : x^\top x \leq 1 \right\}, \quad (1)$$

where $\lambda_{\min}(Q_1)$ is the smallest eigenvalue of matrix Q_1 . Unfortunately, this CQR was underappreciated in that time. Recently, people rediscovered this result; Wang and Xia [46] and Ho-Nguyen and Kilinc-Karzan [25] presented a linear time algorithm to solve the TRS by applying Nesterov's accelerated gradient descent algorithm to (1). We, instead, rewrite the epigraph reformulation for (1) as follows,

$$\min_{x,t} \left\{ t : \frac{1}{2} x^\top (Q_1 - \lambda_{\min}(Q_1)I)x + b_1^\top x + \frac{1}{2} \lambda_{\min}(Q_1) \leq t, x^\top x \leq 1 \right\}.$$

Motivated by the above reformulation, we demonstrate that the GTRS is equivalent to exactly one of the following two convex quadratic reformulations under two different conditions,

$$\begin{aligned} (P_1) \quad & \min_{x,t} \quad \{t : h_1(x) \leq t, h_2(x) \leq t\}, \\ (P_2) \quad & \min_{x,t} \quad \{t : h_3(x) \leq t, f_2(x) \leq 0\}, \end{aligned}$$

where $h_1(x)$, $h_2(x)$ and $h_3(x)$, which will be defined later in Theorem 2.10, and $f_2(x)$ defined in problem (P), are convex but possibly not strongly convex, quadratic functions. To our best knowledge, our proposed CQRs are derived for the first time for the GTRS. The reformulation (P₂) only occurs when the quadratic constraint is convex and thus can be solved by a slight modification of [46, 25] in the accelerated gradient projection method by projecting, in each iteration, the current solution to the ellipsoid instead of the unit ball in the TRS case.

In this paper we focus on the problem reformulation (P₁). Although our CQR can be solved as an SOCP problem [9], it is not efficient when the problem size is large. Our main contribution is based on a recognition that problem (P₁) is equivalent to minimizing the maximum of the two convex quadratic functions in (P₁),

$$(M) \quad \min \{H(x) := \max\{h_1(x), h_2(x)\}\}.$$

We further derive efficient algorithms to solve the above minimax problem. To the best of our knowledge, the current literature lacks studies on such a problem formulation for a large scale setting except using a black box subgradient method with an $O(1/\epsilon^2)$ convergence rate [12], which is really slow. Note that Section 2.3 in Nesterov's book [38] presents a gradient based method with linear convergence rate for solving the minimization problem (M) under the condition that both $h_1(x)$ and $h_2(x)$ are strongly convex. However, Nesterov's algorithms cannot be applied to solve our problem since in our problem setting at least one function of $h_1(x)$ and $h_2(x)$ is not strongly convex. By using the special structure of problem

(M), we derive a steepest descent method in Section 3. More specifically, we choose either the negative gradient when the current point is smooth, or a vector in the subgradient set with the smallest norm (the steepest descent direction) when the current point is nonsmooth as the descent direction, and derive two steepest descent algorithms with two different line search rules accordingly. In the first algorithm we choose a special step size, and in the second algorithm we propose a modified Armijo line search rule. We also prove the global sublinear convergence rate for both algorithms. The first algorithm even admits a global convergence rate of $O(1/\epsilon)$, in the same order as the gradient descent algorithm, which is faster than the subgradient method. In addition, we demonstrate that the first algorithm also admits a local linear convergence rate, by a delicate analysis on the Kurdyka-Łojasiewicz (KL) [6, 11, 33, 18] property for problem (M). We illustrate in our numerical experiments the efficiency of the proposed algorithms when compared with the state-of-the-art methods for GTRS in the literature.

The rest of this paper is organized as follows. In Section 2, we derive an explicit CQR for problem (P) under different conditions and show how to recover an optimal solution of problem (P) from that of the CQR. In Section 3, we reformulate the CQR to a convex nonsmooth unconstrained minimax problem and derive two efficient solution algorithms. We provide convergence analysis for both algorithms. In Section 4, we demonstrate the efficiency of our algorithms from our numerical experiments. We conclude our paper in Section 5.

Notation We use $v(\cdot)$ to denote the optimal value of problem (\cdot) . The matrix transpose of matrix A is denoted by A^\top and inverse of matrix A by A^{-1} , respectively. Let $\mathcal{B}(x, \delta) = \{y : \|y - x\| \leq \delta\}$ denote the ball centered at x with radius δ , where $\|\cdot\|$ denotes the Euclidean norm of a vector.

2 Blanket assumptions and convex quadratic reformulation

In this section, we derive a novel convex quadratic reformulation for problem (P). To avoid some trivial cases, we assume in the following Assumption 2.1, w.l.o.g., the Slater condition holds for problem (P), i.e., there exists at least one interior feasible point. When both $f_1(x)$ and $f_2(x)$ are convex, problem (P) is already a convex quadratic problem. Hence, the assumption that not both $f_1(x)$ and $f_2(x)$ are convex is also without loss of generality. We make the following *blanket assumptions*, Assumptions 2.1–2.3 throughout this paper.

Assumption 2.1. *The Slater condition holds for problem (P) and not both $f_1(x)$ and $f_2(x)$ are convex.*

Assumption 2.2. *The set $I_{PSD} := \{\lambda : Q_1 + \lambda Q_2 \succeq 0\} \cap \mathbb{R}_+$ is not empty, where \mathbb{R}_+ is the nonnegative orthant.*

Assumption 2.3. *The common null space of Q_1 and Q_2 is trivial, i.e., $\text{Null}(Q_1) \cap \text{Null}(Q_2) = \{0\}$.*

Before introducing our CQR, let us first recall the celebrated S-lemma by defining $\tilde{f}_1(x) = f_1(x) + \gamma$ with an arbitrary constant $\gamma \in \mathbb{R}$.

Lemma 2.4 (S-lemma [48, 39]). *The following two statements are equivalent:*

1. *The system of $\tilde{f}_1(x) < 0$ and $f_2(x) \leq 0$ is not solvable;*
2. *There exists $\mu \geq 0$ such that $\tilde{f}_1(x) + \mu f_2(x) \geq 0$ for all $x \in \mathbb{R}^n$.*

Using the S-lemma, the following lemma shows a necessary and sufficient condition under which problem (P) is bounded from below.

Lemma 2.5 (Theorem 4.1 [26]). *When the Slater condition holds, problem (P) is bounded from below if and only if the following system has a solution for λ :*

$$Q_1 + \lambda Q_2 \succeq 0, \lambda \geq 0, b_1 + \lambda b_2 \in \text{Range}(Q_1 + \lambda Q_2).$$

If Assumption 2.2 fails, there exists no nonnegative λ such that $Q_1 + \lambda Q_2 \succeq 0$ and problem (P) is unbounded from below due to Lemma 2.5. We make Assumption 2.3 without loss of generality, because otherwise we can reduce the problem to a case that satisfies Assumption 2.3 or show that the problem admits a simple analytical solution or is unbounded from below (see Appendix A for detailed discussions). So both Assumptions 2.2 and 2.3 are made without loss of generality. In the following of this section, we always assume that the above Assumptions 2.1–2.3 hold true.

It has been shown in [36] that $\{\lambda : Q_1 + \lambda Q_2 \succeq 0\}$ is an interval and thus $\{\lambda : Q_1 + \lambda Q_2 \succeq 0\} \cap \mathbb{R}_+$ is also an interval (if not empty). Under Assumptions 2.1–2.3, we have the following three cases for I_{PSD} .

Condition 2.6. *The set $I_{PSD} = [\lambda_1, \lambda_2]$ with $\lambda_1 < \lambda_2$.*

Condition 2.7. *The set $I_{PSD} = [\lambda_3, \infty)$.*

Condition 2.8. *The set $I_{PSD} = \{\lambda_4\}$ is a singleton.*

Note that Condition 2.7 occurs only when Q_2 is positive semidefinite. Under Condition 2.8, Q_1 and Q_2 may not be SD and may have 2×2 block pairs in a canonical form under congruence [29]. In this case, when λ is given, the authors in [29] showed how to recover an optimal solution if the optimal solution is attainable, and how to obtain an ϵ optimal solution if the optimal solution is unattainable. So in the following, we mainly focus on the cases where either Condition 2.6 or 2.7 is satisfied.

Lemma 2.9. *Under Condition 2.6 or 2.7, problem (P) is bounded from below.*

Proof. Under Condition 2.6 or 2.7, there exists a λ_0 such that $Q_1 + \lambda_0 Q_2 \succ 0$ and $\lambda_0 \geq 0$, which further implies $b_1 + \lambda_0 b_2 \in \text{Range}(Q_1 + \lambda_0 Q_2)$ as $Q_1 + \lambda_0 Q_2$ is nonsingular. With Lemma 2.5, we complete the proof. \square

2.1 Convex quadratic reformulation for GTRS

It is obvious that problem (P) is equivalent to its epigraph reformulation as follows,

$$(P_0) \min\{t : f_1(x) \leq t, f_2(x) \leq 0\}.$$

Now we are ready to present the main result of this section.

Theorem 2.10. *Under the blanket assumptions, by defining $h_i(x) = f_1(x) + \lambda_i f_2(x)$, $i = 1, 2, 3$, we can reformulate problem (P) to a convex quadratic problem under Conditions 2.6 and 2.7, respectively:*

1. *Under Condition 2.6, problem (P) is equivalent to the following convex quadratic problem,*

$$(P_1) \min_{x,t} \{t : h_1(x) \leq t, h_2(x) \leq t\};$$

2. *Under Condition 2.7, problem (P) is equivalent to the following convex quadratic problem,*

$$(P_2) \min_{x,t} \{t : h_3(x) \leq t, f_2(x) \leq 0\} = \min_x \{h_3(x) : f_2(x) \leq 0\}.$$

Proof. Let us first consider the case where Condition 2.6 holds. Due to Lemma 2.9, (P_1) is bounded from below. Together with the assumed Slater conditions, problem (P_1) admits the same optimal value as its Lagrangian dual [9]. Due to the S-lemma, problem (P) also has the same optimal value as its Lagrangian dual [45],

$$(D) \max_{\mu \geq 0} \min_x f_1(x) + \mu f_2(x).$$

Under Condition 2.6, i.e., $I_{PSD} = [\lambda_1, \lambda_2]$ with $\lambda_1 < \lambda_2$, it is easy to show that (P_1) is a relaxation of (P_0) since they have the same objective function and the feasible region of (P_1) contains that of (P_0) (note that $f_1 \leq t$ and $f_2 \leq 0$ imply that $f_1(x) - t + uf_2(x) \leq 0$ for all $u \geq 0$). Thus,

$$v(P_1) \leq v(P_0) = v(P). \quad (2)$$

The Lagrangian dual problem of (P_1) is

$$(D_1) \quad \max_{s_1, s_2 \geq 0} \min_{x, t} t + (s_1 + s_2)(f_1(x) - t) + (\lambda_1 s_1 + \lambda_2 s_2)f_2(x).$$

For any primal and dual optimal solution pair (x^*, μ^*) of (P) and (D) , due to $\mu^* \in [\lambda_1, \lambda_2]$ as $Q_1 + \mu^* Q_2 \succeq 0$ from Lemma 2.5, we can always find a convex combination $\lambda_1 \bar{s}_1 + \lambda_2 \bar{s}_2 = \mu^*$ with $\bar{s}_1 + \bar{s}_2 = 1$. Hence (x^*, \bar{s}, t) , with an arbitrary t , is a feasible solution to (D_1) and the objective value of problem (D_1) at (x^*, \bar{s}, t) is the same with the optimal value of (D) . This in turn implies

$$v(D_1) \geq v(D). \quad (3)$$

Since (P_1) is convex and Slater condition is satisfied (letting t go to infinity gives a strictly feasible point), $v(P_1) = v(D_1)$. Finally, by combining (2) and (3), we have $v(P_1) = v(D_1) \geq v(D) = v(P) = v(P_0) \geq v(P_1)$. So all inequalities above become equalities and thus (P_1) is equivalent to (P) .

Statement 2 can be proved in a similar way and its proof is thus omitted. \square

Remark 2.11. *Reformulation (P_2) generalizes the approaches in [16, 46, 25] for the classical TRS with the unit ball constraint to the GTRS with a general convex quadratic constraint.*

To our best knowledge, there is no method in the literature to compute λ_1 and λ_2 in Condition 2.6 for general Q_1 and Q_2 . However, there exist efficient methods in the literature to compute λ_1 and λ_2 when a λ_0 is given such that $Q_1 + \lambda_0 Q_2 \succ 0$ is satisfied. More specifically, the method mentioned in Section 2.4.1 in [5] gives a way to compute λ_1 and λ_2 : first detect a λ_0 such that $Q_0 := Q_1 + \lambda_0 Q_2 \succ 0$, and then compute λ_1 and λ_2 by some generalized eigenvalues for a definite matrix pencil that are nearest to 0. Please refer to [22] for one of the state-of-the-art methods for detecting λ_0 . We can also find another iterative method in Section 5 [36] to compute $\lambda_0 \in \text{int}(I_{PSD})$ by reducing the length of an interval $[\bar{\lambda}_1, \bar{\lambda}_2] \supset I_{PSD}$. We next report our new method to compute λ_1 and λ_2 , which is motivated by [40]. Our first Step is also to find a λ_0 such that $Q_0 := Q_1 + \lambda_0 Q_2 \succ 0$. Then if Q_2 is negative semidefinite, under Assumption 2.1–2.3, Condition 2.6 holds if and only if Q_1 is positive definite, the interval is then just $[0, u_0]$, where u_0 is the maximum generalized eigenvalue of $Q_1 + uQ_2$. Otherwise, we compute the maximum generalized eigenvalues for $Q_2 + \mu Q_0$ and $-Q_2 + \mu Q_0$, denoted by u_1 and u_2 , respectively. Note that both $u_1 > 0$ and $u_2 > 0$ due to $Q_0 \succ 0$ and Q_2 has at least one negative eigenvalue and one positive eigenvalue (otherwise λ_2 can be $+\infty$). So we have

$$Q_1 + \left(\frac{1}{u_1} + \lambda_0\right)Q_2 \succeq 0 \quad \text{and} \quad Q_1 + \left(-\frac{1}{u_2} + \lambda_0\right)Q_2 \succeq 0.$$

Thus $Q_1 + \eta Q_2 \succeq 0$ for all $\eta \in [\lambda_0 - \frac{1}{u_2}, \lambda_0 + \frac{1}{u_1}]$, which implies $\lambda_1 = \lambda_0 - \frac{1}{u_2}$ and $\lambda_2 = \lambda_0 + \frac{1}{u_1}$. In particular, when one of Q_1 and Q_2 is positive definite, we can skip the step of detecting the definiteness, which would save significant time in implementation.

In fact, when λ_0 is given, we only need to compute one extreme eigenvalues, either λ_1 or λ_2 , to obtain our convex quadratic reformulation. To see this, we first note that under the blanket assumptions and Condition 2.6, $Q_1 + \lambda Q_2 \succ 0$ for all $\lambda \in (\lambda_1, \lambda_2)$. Now let us define $x(\lambda) = -(Q_1 + \lambda Q_2)^{-1}(b_1 + \lambda b_2)$ for all $\lambda \in \text{int}(I_{PSD})$, noting that $(Q_1 + \lambda Q_2)^{-1}$ is well-defined for all $\lambda \in (\lambda_1, \lambda_2)$, and $\gamma(\lambda) = f_2(x(\lambda))$. In fact, there are Newton type methods in the literature (e.g., [36]) for solving the GTRS by finding the optimal λ through $\gamma(\lambda) = 0$. However, each Step in [36] involves solving a linear system $-(Q_1 + \lambda Q_2)^{-1}(b_1 + \lambda b_2)$,

which is time consuming for high-dimension settings. Moreover, the Newton's method does not converge in the so called hard case¹. On the other hand, for easy case, an initial λ_0 in I_{PSD} is also needed as a safeguard to guarantee the positive definiteness of $Q_1 + \lambda_0 Q_2$ [36]. It is shown in [36] that $\gamma(\lambda)$ is either a strictly decreasing function or a constant in $\text{int}(I_{PSD})$. Following [5], we have the following three cases: if $\gamma(\lambda_0) > 0$, the optimal λ^* locates in $[\lambda_0, \lambda_2]$; if $\gamma(\lambda_0) = 0$, $x(\lambda_0)$ is an optimal solution; and if $\gamma(\lambda_0) < 0$, the optimal λ^* locates in $[\lambda_1, \lambda_0]$. Hence we have the following corollary, whose proof is similar to that in Theorem 2.10 and thus omitted.

Corollary 2.12. *Define $h_i(x) = f_1(x) + \lambda_i f_2(x)$, $i = 0, 1, 2$. Under the blanket assumptions and Condition 2.6, the following results hold true.*

1. *If $\gamma(\lambda_0) > 0$, problem (P) is equivalent to the following convex quadratic problem,*

$$(\bar{P}_1) \min_{x,t} \{t : h_0(x) \leq t, h_2(x) \leq t\}.$$

2. *If $\gamma(\lambda_0) = 0$, $x(\lambda_0) = -(Q_1 + \lambda_0 Q_2)^{-1}(b_1 + \lambda_0 b_2)$ is the optimal solution.*

3. *If $\gamma(\lambda_0) < 0$, problem (P) is equivalent to the following convex quadratic problem,*

$$(\underline{P}_1) \min_{x,t} \{t : h_1(x) \leq t, h_0(x) \leq t\}.$$

Since both (\bar{P}_1) and (\underline{P}_1) have a similar form to (P_1) and can be solved in a way similar to the solution approach for (P_1) , we only discuss how to solve (P_1) in the following.

2.2 Recovery of optimal solutions

In this subsection, we will discuss the recovery of an optimal solution to problem (P) from an optimal solution to reformulation (P_1) . Before that, we first introduce the following lemma. Let us assume from now on $h_i(x) = \frac{1}{2}x^\top A_i x + a_i^\top x + r_i$, $i = 1, 2$.

From Lemma 2.9, Condition 2.6 implies the boundedness of problem (P) and thus the optimal solution is always attainable [29]. In the following theorem, we show how to recover the optimal solution of problem (P) from an optimal solution of problem (P_1) .

Theorem 2.13. *Assume that Condition 2.6 holds and (x^*, t) is an optimal solution of problem (P_1) . Then an optimal solution of problem (P) can be obtained in the following ways:*

1. *If i) $h_1(x^*) = t$ and $h_2(x^*) = t$ or ii) A_1 is nonsingular and $h_1(x^*) = t$ and $h_2(x^*) < t$, then x^* is an optimal solution to (P);*
2. *Otherwise i) $h_1(x^*) < t$ and $h_2(x^*) = t$ or ii) A_1 is singular, $h_1(x^*) = t$ and $h_2(x^*) < t$. In case i), for any vector $v_l \in \text{Null}(A_2)$, letting $\tilde{\theta}$ be a solution of the following equation,*

$$h_1(x^* + \theta v_l) = \frac{1}{2}v_l^\top A_1 v_l \theta^2 + (v_l^\top A_1 x^* + a_1^\top v_l)\theta + h_1(x^*) = t, \quad (4)$$

then $\{\tilde{x} : \tilde{x} = x^ + \tilde{\theta} v_l, v_l \in \text{Null}(A_2), \tilde{\theta} \text{ is a solution of (4)}\}$ forms the set of optimal solutions of (P). The recovery for case ii) follows a symmetric rule.*

Proof. Note that at least one of $h_1(x^*) \leq t$ and $h_2(x^*) \leq t$ takes equality. Then we prove the theorem for the following two cases:

¹The definition here follows [36]. In fact, the definitions of hard case and easy case of the GTRS are similar to those of the TRS. More specifically, if the null space of the Hessian matrix, $Q_1 + \lambda^* Q_2$, with λ^* being the optimal Lagrangian multiplier of problem (P), is orthogonal to $b_1 + \lambda^* b_2$, we are in the hard case; otherwise we are in the easy case.

1. If $h_1(x^*) = t$ and $h_2(x^*) = t$, then $f_1(x^*) + \lambda_2 f_2(x^*) = f_1(x^*) + \lambda_1 f_2(x^*)$. Hence $f_2(x^*) = 0$ due to $\lambda_2 - \lambda_1 > 0$. So we have $f_1(x^*) = t - \lambda_1 f_2(x^*) = t$. If A_1 is nonsingular, then we have $A_1 \succ 0$ from $A_1 \succeq 0$. Then we must have $\lambda_1 = 0$ (this is the case that the left end point of the interval $\{\lambda : Q_1 + \lambda Q_2 \succeq 0\}$ is negative) and thus $f_1(x^*) = t - \lambda_1 f_2(x^*) = t$. Meanwhile, $h_1(x^*) = t > h_2(x^*)$ implies that $f_1(x^*) + \lambda_1 f_2(x^*) > f_1(x^*) + \lambda_2 f_2(x^*)$, i.e., $f_2(x^*) < 0$.

As the optimal value of problem (P) must be not smaller than the optimal value of its relaxation (P₁), the fact that $f_1(x^*) = t$ and $f_2(x^*) \leq 0$, which means the feasibility of x^* , indicates x^* is an optimal solution for problem (P).

2. We first consider i) $h_1(x^*) < t$ and $h_2(x^*) = t$. First note that A_2 has a nontrivial null space, i.e., $\text{Null}(A_2) \neq \{0\}$, which is true because I_{PSD} is an interval. Note also that Condition 2.6 and Assumption 2.3 imply that $Q_1 + \frac{\lambda_1 + \lambda_2}{2} Q_2 \succ 0$, i.e., $\frac{A_1 + A_2}{2} \succ 0$. Then we have $d^\top A_1 d > 0$ for all nonzero vector $d \in \text{Null}(A_2)$. We also claim that $a_2^\top d = 0$. Otherwise, setting d such that $a_2^\top d < 0$ (This can be done since we have $a_2^\top(-d) < 0$ if $a_2^\top d > 0$.) yields

$$h_2(x^* + d) = h_2(x^*) + \frac{1}{2} d^\top A_2 d + (x^*)^\top A_2 d + a_2^\top d = h_2(x^*) + a_2^\top d < t,$$

where the second equality is due to $d \in \text{Null}(A_2)$ and $h_1(x^* + d) < t$ for any sufficiently small d because $h_1(x^*) < t$. This implies that (x^*, t) is not optimal, which is a contradiction. Equation (4) has two solutions due to the positive parameter before the quadratic term, i.e., $v_l^\top A_1 v_l > 0$ and the negative constant, i.e., $h_1(x^*) - t < 0$. With the definition of $\tilde{\theta}$, we know $h_1(\tilde{x}) = t$ and $h_2(\tilde{x}) = t$. This further implies $f_1(\tilde{x}) = t$ and $f_2(\tilde{x}) = 0$, i.e., \tilde{x} is an optimal solution to (P).

The recovery for case ii) follows a symmetric rule because case ii) is symmetric to case i).

□

Remark 2.14. In Item 2 of the above proof, $a_2^\top d = 0$ indicates that problem (P) is in the hard case.

We next illustrate our recovery approach for the following simple example,

$$\min\{3x_1^2 - \frac{1}{2}x_2^2 - x_2 : -x_1^2 + \frac{1}{2}x_2^2 + x_2 + 1 \leq 0\}.$$

Note that, for this example, Condition 2.6 holds, $\lambda_1 = 1$ and $\lambda_2 = 3$. Then we have the following CQR,

$$\min\{t : 2x_1^2 + 1 \leq t, x_2^2 + 2x_2 + 3 \leq t\}.$$

An optimal solution of the CQR is $x = (0, -1)^\top$, $t = 2$. However, this x is not feasible to (P). Using the approach in Theorem 2.13, we obtain an optimal solution $\tilde{x} = (\frac{\sqrt{2}}{2}, -1)^\top$ to problem (P). In fact, this instance is in the hard case since the optimal Lagrangian multiplier, $\lambda^* = 3$, is at the end of the interval $\{\lambda : Q_1 + \lambda Q_2 \succeq 0, \lambda \geq 0\}$ and $a + \lambda^* b \in \text{Range}(Q_1 + \lambda^* Q_2)$.

We finally point out that our method can be extended to the following variants of GTRS with equality constraint and interval constraint,

$$\begin{aligned} \text{(EP)} \quad & \min \quad f_1(x) := \frac{1}{2}x^\top Q_1 x + b_1^\top x \\ & \text{s.t.} \quad f_2(x) := \frac{1}{2}x^\top Q_2 x + b_2^\top x + c = 0, \end{aligned}$$

and

$$\begin{aligned} \text{(IP)} \quad & \min \quad f_1(x) := \frac{1}{2}x^\top Q_1 x + b_1^\top x \\ & \text{s.t.} \quad c_1 \leq f_2(x) := \frac{1}{2}x^\top Q_2 x + b_2^\top x \leq c_2. \end{aligned}$$

It is shown in [40, 29] that (IP) can be reduced to (EP) with minor computation. It is obvious that all our previous results for inequality constrained GTRS hold for (EP) if we remove the non-negativity requirement for λ in I_{PSD} , i.e., $I_{PSD} = \{\lambda : Q_1 + \lambda Q_2 \succeq 0\}$. We thus omit detailed discussion for (EP) to save space.

3 Efficient algorithms in solving the minimax problem reformulation of the CQR

In this section, we propose efficient algorithms to solve the GTRS under Condition 2.6. As shown in Theorem 2.10 and Corollary 2.12, the GTRS is equivalent to (P_1) or either (\bar{P}_1) or (\underline{P}_1) . The three problems have similar forms and can be solved by the following proposed method in this section. Hence, to save space, we only consider solution algorithms for (P_1) in this section.

The convex quadratic problem (P_1) can be cast as an SOCP problem and solved by many existing solvers, e.g., CVX [21], CPLEX [1] and MOSEK [2]. However, the SOCP reformulation is not very efficient when the dimension is large (e.g., the SOCP solver will take about 1,000 seconds to solve a problem of dimension 10,000)². Fortunately, due to its simple structure, (P_1) is equivalent to the following minimax problem of two convex quadratic functions

$$(M) \quad \min\{H(x) := \max\{h_1(x), h_2(x)\}\}.$$

Hence we aim to derive an efficient method to solve the above minimax problem, thus solving the original GTRS. Our method is a steepest descent method to find a critical point with $0 \in \partial H(x)$. It is well known that such a critical point is an optimal solution of problem (M).

The following theorem tells us how to find the steepest descent direction.

Theorem 3.1. *Let $g_1 = \nabla h_1(x)$ and $g_2 = \nabla h_2(x)$. If g_1 and g_2 have opposite directions, i.e., $g_1 = -tg_2$ for some constant $t > 0$ and $h_1(x) = h_2(x)$ or if $g_i = 0$ and $h_i(x) \geq h_j(x)$ for $i \neq j$, $i, j \in \{1, 2\}$, then x is a global optimal solution. Otherwise we can always find the steepest descent direction d in the following way:*

1. when $h_1(x) \neq h_2(x)$, $d = -g_1$ if $h_1(x) > h_2(x)$ and otherwise $d = -g_2$;
2. when $h_1(x) = h_2(x)$, $d = -(\alpha g_1 + (1 - \alpha)g_2)$, where α is defined in the following three cases:
 - (a) $\alpha = 0$, if $g_1^\top g_1 \geq g_1^\top g_2 \geq g_2^\top g_2$,
 - (b) $\alpha = 1$, if $g_1^\top g_1 \leq g_1^\top g_2 \leq g_2^\top g_2$,
 - (c) $\alpha = \frac{g_2^\top g_2 - g_1^\top g_2}{g_1^\top g_1 + g_2^\top g_2 - 2g_1^\top g_2}$, if $g_1^\top g_2 < g_2^\top g_2$ and $g_1^\top g_2 \leq g_1^\top g_1$ or $g_1^\top g_2 \leq g_2^\top g_2$ and $g_1^\top g_2 < g_1^\top g_1$.

Proof. If $h_1(x) = h_2(x)$ and $g_1 = -tg_2$, then $0 \in \partial H(x)$. Hence, by the definition of subgradient, we have

$$H(y) \geq H(x) + 0^\top(y - x) = H(x), \quad \forall y,$$

which further implies that x is the optimal solution.

If $g_i = 0$ and $h_i(x) \geq h_j(x)$ for $i \neq j$, $i, j \in \{1, 2\}$, then for all $y \neq x$, we have $H(y) \geq h_i(y) \geq h_i(x) = H(x)$, i.e., x is a global optimal solution.

Otherwise we have the following three cases:

1. When $h_1(x) \neq h_2(x)$, (suppose, w.l.o.g., $h_1(x) > h_2(x)$), for all $y \in \mathcal{B}(x, \delta)$ with $\mathcal{B}(x, \delta) \subset \{u : h_2(u) < h_1(u)\}$, we have $H(y) = h_1(y)$ and thus $H(x)$ is differentiable at x and smooth in the neighbourhood of x , where $\mathcal{B}(x, \delta)$ denotes the ball centered at x with radius δ . Hence, $d = -g_1$ if $h_1(x) > h_2(x)$. Symmetrically, the case with $h_2(x) > h_1(x)$ can be proved in the same way.
2. When $h_1(x) = h_2(x)$, the steepest descent direction can be found by solving the following problem:

$$\min_{\|y\| \leq 1} \max_{g \in \partial H(x)} g^\top y. \quad (5)$$

²The code was implemented in Matlab 2016a, 64bit and run on a Linux machine with 48GB RAM, 2600MHz cpu and 64-bit CentOS release 7.1.1503, which is the same with the numerical section.

Because $g^T y$ is bilinear, the first constraint set $\{y : \|y\| \leq 1\}$ is convex and compact and the second constraint set $\partial H(x)$ is convex, by Sion's minimax theorem [43] (see also Appendix B), we have

$$\min_{\|y\| \leq 1} \max_{g \in \partial H(x)} g^T y = \max_{g \in \partial H(x)} \min_{\|y\| \leq 1} g^T y = \max_{g \in \partial H(x)} -\|g\|,$$

where the last equality is due to $\operatorname{argmin}_{\|y\| \leq 1} g^T y = -g/\|g\|$. The above problem (5) is then equivalent to $\min_{g \in \partial H(x)} \|g\|^2$, which is exactly the following problem in minimizing a quadratic function of α ,

$$\min_{0 \leq \alpha \leq 1} (\alpha g_1 + (1 - \alpha) g_2)^\top (\alpha g_1 + (1 - \alpha) g_2). \quad (6)$$

The first order optimality condition of the above objective function gives rise to $\alpha = \frac{g_2^\top g_2 - g_1^\top g_2}{g_1^\top g_1 + g_2^\top g_2 - 2g_1^\top g_2}$. Then if $\frac{g_2^\top g_2 - g_1^\top g_2}{g_1^\top g_1 + g_2^\top g_2 - 2g_1^\top g_2}$ is in the interval $[0, 1]$, the optimal α is given by $\frac{g_2^\top g_2 - g_1^\top g_2}{g_1^\top g_1 + g_2^\top g_2 - 2g_1^\top g_2}$. Otherwise, (6) takes its optimal solution on its boundary. By noting that $g_1^\top g_1 + g_2^\top g_2 - 2g_1^\top g_2 = \|g_1 - g_2\|^2 \geq 0$, we have, in particular,

- $\alpha = 1$, when $\frac{g_2^\top g_2 - g_1^\top g_2}{g_1^\top g_1 + g_2^\top g_2 - 2g_1^\top g_2} > 1$, i.e., $g_2^\top g_2 > g_1^\top g_2$ and $g_1^\top g_1 < g_1^\top g_2$, and
- $\alpha = 0$, when $\frac{g_2^\top g_2 - g_1^\top g_2}{g_1^\top g_1 + g_2^\top g_2 - 2g_1^\top g_2} < 0$, i.e., $g_1^\top g_2 > g_2^\top g_2$ (and thus $g_1^\top g_1 > g_1^\top g_2$).

Note that $g_1^\top g_1 + g_2^\top g_2 - 2g_1^\top g_2 = \|g_1 - g_2\|^2 \geq 0$ also implies that we cannot have $g_1^\top g_2 > g_2^\top g_2$ and $g_1^\top g_2 \geq g_1^\top g_1$ or $g_1^\top g_2 \geq g_2^\top g_2$ and $g_1^\top g_2 > g_1^\top g_1$. And $g_1^\top g_2 \geq g_2^\top g_2$ and $g_1^\top g_2 \geq g_1^\top g_1$ if and only if $g_1 = g_2$. Hence, by including the case that $g_1 = g_2$ into (a) and (b), we complete the proof. \square

Remark 3.2. *The above theorem shows that the steepest descent direction at each point with $h_1(x) = h_2(x)$ is either the one with the smaller norm between $\nabla h_1(x)$ and $\nabla h_2(x)$ or the negative convex combination d of $\nabla h_1(x)$ and $\nabla h_2(x)$ such that $\nabla h_1(x)^\top d = \nabla h_2(x)^\top d$.*

Using the descent direction **and a close variant** presented in Theorem 3.1, we propose two algorithms to solve the minimax problem (M), respectively, in Algorithms 1 and 2: we first compute a descent direction by the idea in Theorem 3.1, apply then two different line search rules for choosing the step size, and finally terminate the algorithm if some termination criterion is met. The advantage of our algorithms is that each iteration is very cheap, thus yielding, with an acceptable iterate number, a low cost in CPU time. The most expensive operation in each iteration is to compute several matrix vector products, which could become cheap when the matrices are sparse.

3.1 Line search with a special step size

In the following, we first derive a local linear convergence rate for Algorithm 1 and then demonstrate a global sublinear convergence rate for Algorithm 1. We analyze the local convergence rate by studying the growth in the neighbourhood of any optimal solution to $H(x)$ in (M). In fact, $H(x)$ belongs to a more general class of piecewise quadratic functions. Error bounds and the KL property, which are two widely used techniques for convergence analysis, have been studied in the literature, for several kinds of piecewise quadratic functions, see [32, 34, 52]. However, these results are based on piecewise quadratic functions separated by polyhedral sets, which is not the case of $H(x)$. Li et al. [30] demonstrated that KL property holds for the maximum of finite polynomials, but their KL exponent depends on the problem dimension and is close to one, which leads to a very weak sublinear convergence rate. Gao et al. [18] studied the KL exponent for the TRS with the constraint replaced by an equality constraint $x^\top x = 1$. However, their technique depends on the convexity of the function $x^\top x$ and cannot be applied to analyze

Algorithm 1 Line search with a special step size for Problem (M)

Input: Parameters in the minimax problem (M)

```

1: Initialize  $x_0$ 
2: for  $k = 0, 1, \dots$ , do
3:   if  $h_1(x_k) > h_2(x_k)$  then
4:     set  $d_k = -\nabla h_1(x_k)$ 
5:   else if  $h_1(x_k) < h_2(x_k)$  then
6:     set  $d_k = -\nabla h_2(x_k)$ 
7:   else
8:     set  $d_k$  corresponding to Theorem 3.1, item 2
9:   end if
10:  if termination criterion is met then return
11:  end if
12:  Choose a step size  $\beta_k$  according to Theorem 3.5
13:  Update  $x_{k+1} = x_k + \beta_k d_k$ 
14: end for
    
```

our problem. A significant result of this paper is to establish the KL exponent of $1/2$ for function $H(x)$ when $\min_x H(x) > \max_i \{\min_x h_1(x), \min_x h_2(x)\}$. With this KL exponent, we are able to illustrate the linear convergence of our first algorithm with the proposed special step size.

For completeness, we give a definition of the KL property in the following.

Definition 3.3. [6, 31, 18] Let $f : \mathbb{R}^n \rightarrow \mathbb{R} \cup \{+\infty\}$ be a proper lower semicontinuous function satisfying that the restriction of f to its domain is a continuous function. The function f is said to have the KL property at $\bar{x} \in \{x : 0 \in \partial f(x)\}$, if there exist $C, \epsilon > 0$ and $\theta \in [0, 1)$ such that

$$C \|y\| \geq |f(x) - f(\bar{x})|^\theta, \quad \forall x \in B(\bar{x}, \epsilon), \quad \forall y \in \partial f(x),$$

where θ is known as the KL exponent.

Under Condition 2.6, we know that there exists $\lambda_0 \geq 0$ such that $Q_1 + \lambda_0 Q_2 \succ 0$ and thus $b_1 + \lambda_0 b_2 \in \text{Range}(Q_1 + \lambda_0 Q_2)$ due to the non-singularity of $Q_1 + \lambda_0 Q_2$. Hence from Lemma 2.5, problem (P) (and thus problem (P₁)) is bounded from below. It follows that the two matrices are SD and further that the optimal solution of problem (P) is attainable [29]. This further implies that problem (P₁) is bounded from below with its optimal solution attainable. Assuming that x^* is an optimal solution, the following theorem shows that the KL inequality holds with an exponent of $1/2$ at x^* under some mild conditions.

Theorem 3.4 (KL property for $H(x)$). Assume that $\min h_1(x) < \min H(x)$ and $\min h_2(x) < \min H(x)$. Then for any $x^* \in \{x : \partial H(x) = 0\}$, there exist $C, \epsilon > 0$ (depending on x^*) such that

$$C \|y\| \geq |H(x) - H(x^*)|^{1/2}, \quad \forall x \in B(x^*, \epsilon), \quad \forall y \in \partial H(x), \quad (7)$$

Proof. Note that $\min h_1(x) < \min H(x)$ and $\min h_2(x) < \min H(x)$ imply that, for any $x^* \in \{x : \partial H(x) = 0\}$, $\nabla h_1(x^*) \neq 0$ and $\nabla h_2(x^*) \neq 0$, respectively. Assume $L = \max\{\lambda_{\max}(A_1), \lambda_{\max}(A_2)\}$. We carry out our proof by considering the following two cases.

1. For any point with $h_1(x) \neq h_2(x)$, w.l.o.g., assuming $h_1(x) > h_2(x)$ gives rise to $\partial H(x) = \{\nabla h_1(x)\}$. Let $x^* = \operatorname{argmin}_{y \in \{y : \partial H(y) = 0\}} \|x - y\|$, i.e., x^* is the projection of x onto the optimality solution set. Hence, by noting that h_1 is active at x^* , we have

$$\begin{aligned}
 |H(x) - H(x^*)| &= \frac{1}{2}(x - x^*)^\top A_1(x - x^*) + (x^*)^\top A_1(x - x^*) + a_1^\top(x - x^*) \\
 &\leq \frac{1}{2}L \|x - x^*\|^2 + \|\nabla h_1(x^*)\| \|x - x^*\|.
 \end{aligned}$$

On the other hand, $\nabla h_1(x) = A_1 x + a_1$ and

$$\begin{aligned} \|\nabla h_1(x)\|^2 &= \|\nabla h_1(x) - \nabla h_1(x^*) + \nabla h_1(x^*)\|^2 \\ &= (x - x^*)^\top A_1 A_1 (x - x^*) + \|\nabla h_1(x^*)\|^2 + 2(\nabla h_1(x^*))^\top A_1 (x - x^*) \\ &\geq \|\nabla h_1(x^*)\|^2 - 2L \|\nabla h_1(x^*)\| \|x - x^*\|. \end{aligned}$$

Define $\epsilon_0 = \min\{1, \frac{\|\nabla h_1(x^*)\|}{4L}\}$. As $\nabla h_1(x^*) \neq 0$, for all $x \in \mathcal{B}(x^*, \epsilon_0)$, we then have

$$|H(x) - H(x^*)| \leq \frac{1}{2} L \epsilon_0^2 + \|\nabla h_1(x^*)\| \epsilon_0 \leq \frac{9}{32L} \|\nabla h_1(x^*)\|^2$$

and

$$\|\nabla h_1(x)\|^2 \geq \|\nabla h_1(x^*)\|^2 - 2L \|\nabla h_1(x^*)\| \epsilon_0 \geq \frac{1}{2} \|\nabla h_1(x^*)\|^2.$$

Hence $|H(x) - H(x^*)|^{\frac{1}{2}} \leq \sqrt{\frac{9}{32L}} \|\nabla h_1(x^*)\| \leq \frac{3}{4\sqrt{L}} \|\nabla h_1(x^*)\|$. So we have the following inequality,

$$|H(x) - H(x^*)|^{1/2} \leq C_0 \|y\|,$$

for all $y \in \partial H(x)$ (here $\{\nabla h_1(x)\} = \partial H(x)$) with $C_0 = \frac{3}{4\sqrt{L}}$.

2. Consider next a point x with $h_1(x) = h_2(x)$. Define $h_\alpha(x) = \alpha h_1(x) + (1 - \alpha) h_2(x)$, for some parameter $\alpha \in [0, 1]$. Let $I = \{i \mid (\nabla h_1(x^*))_i \neq 0\}$. The optimality condition $0 \in \partial H(x^*)$ implies that there exists some $\alpha_0 \in [0, 1]$ such that $\alpha_0 \nabla h_1(x^*) + (1 - \alpha_0) \nabla h_2(x^*) = 0$. Note that $\nabla h_1(x^*) \neq 0$ and $\nabla h_2(x^*) \neq 0$ as assumed and thus $\alpha_0 \in (0, 1)$. Define

$$j = \operatorname{argmax}_i \{ |(\nabla h_1(x^*))_i|, i \in I \}, \quad M_1 = |(\nabla h_1(x^*))_j| \text{ and } M_2 = |(\nabla h_2(x^*))_j|.$$

Note that $\alpha_0 \nabla h_1(x^*) + (1 - \alpha_0) \nabla h_2(x^*) = 0$ implies that $\alpha_0 M_1 = (1 - \alpha_0) M_2$. W.l.o.g, assume $M_1 \geq M_2$ and thus $\alpha_0 \leq \frac{1}{2}$. Since $A_1 x$ ($A_2 x$, respectively) is a continuous function of x , there exists an $\epsilon_1 > 0$ ($\epsilon_2 > 0$, respectively) such that for any $x \in \mathcal{B}(x^*, \epsilon_1)$ ($x \in \mathcal{B}(x^*, \epsilon_2)$, respectively), $\frac{3}{2} M_1 \geq |(\nabla h_1(x))_j| > \frac{1}{2} M_1$ ($\frac{3}{2} M_2 \geq |(\nabla h_2(x))_j| > \frac{1}{2} M_2$, respectively). Let $\epsilon_3 = \min\{\epsilon_1, \epsilon_2\}$. Then we have the following two subcases.

- (a) For all $x \in \mathcal{B}(x^*, \epsilon_3)$ and $\alpha \in [0, \frac{1}{4}\alpha_0]$, noting that $h_1(x) = h_2(x)$, we have

$$\begin{aligned} \|\nabla h_\alpha(x)\| &\geq -\alpha |(\nabla h_1(x))_j| + (1 - \alpha) |(\nabla h_2(x))_j| \\ &\geq -\frac{3}{2} \alpha M_1 + \frac{1}{2} (1 - \alpha) M_2 \\ &\geq -\frac{3}{8} \alpha_0 M_1 + \frac{3}{8} (1 - \alpha_0) M_2 + (\frac{1}{8} + \frac{1}{8} \alpha_0) M_2 \\ &= (\frac{1}{8} + \frac{1}{8} \alpha_0) M_2. \end{aligned}$$

The third inequality is due to the fact that $-\frac{3}{2} \alpha M_1 + \frac{1}{2} (1 - \alpha) M$ is a decreasing function of α and the last equality is due to $\alpha_0 M_1 = (1 - \alpha_0) M_2$. Symmetrically, for $\alpha \in [1 - \frac{1 - \alpha_0}{4}, 1]$, we have $|(\nabla h_\alpha(x))_j| \geq (\frac{3}{8} - \frac{1}{4} \alpha_0) M_1$. Combining these two cases and $\alpha_0 \leq \frac{1}{2}$ yields $\|\nabla h_\alpha(x)\| \geq \frac{1}{8} M_2$.

On the other hand, $H(x) - H(x^*) \rightarrow 0$ as $x \rightarrow x^*$. More specifically, we have

$$\begin{aligned} |H(x) - H(x^*)| &= \frac{1}{2} (x - x^*)^\top A_1 (x - x^*) + (x^*)^\top A_1 (x - x^*) + a_1^\top (x - x^*) \\ &\leq \frac{1}{2} L \|x - x^*\|^2 + \|\nabla h_1(x^*)\| \|x - x^*\| \\ &\leq \left(\frac{1}{2} L \epsilon_3^2 + \|\nabla h_1(x^*)\| \right) \|x - x^*\|. \end{aligned}$$

Letting $\epsilon_4 = \min\{\epsilon_3, 1\}$ leads to $\frac{M_2^2}{32L\epsilon_3^2+64\|\nabla h_1(x^*)\|}|H(x) - H(x^*)| \leq \|\nabla h_\alpha(x)\|^2$. So

$$|H(x) - H(x^*)|^{1/2} \leq C_1 \|\nabla h_\alpha(x)\|, \quad \forall \alpha \in [0, \frac{1}{4}\alpha_0] \cup [1 - \frac{1-\alpha_0}{4}, 1], \quad \forall x \in \mathcal{B}(x^*, \epsilon_4)$$

where $C_1 = \frac{\sqrt{32L\epsilon_3^2+64\|\nabla h_1(x^*)\|}}{M_2}$.

- (b) Next let us consider the case with $\alpha \in [\frac{\alpha_0}{4}, 1 - \frac{1-\alpha_0}{4}]$. In this case, defining $A_\alpha = \alpha A_1 + (1-\alpha)A_2$ and $a_\alpha = \alpha a_1 + (1-\alpha)a_2$ gives rise to

$$\begin{aligned} \|\nabla h_\alpha(x)\|^2 &= \|\nabla h_\alpha(x) - \nabla h_\alpha(x^*) + \nabla h_\alpha(x^*)\|^2 \\ &= (x - x^*)^\top A_\alpha A_\alpha (x - x^*) + \|\nabla h_\alpha(x^*)\|^2 + 2(\nabla h_\alpha(x^*))^\top A_\alpha (x - x^*) \end{aligned}$$

and since $h_1(x) = h_2(x)$ and $h_1(x^*) = h_2(x^*)$,

$$\begin{aligned} |H(x) - H(x^*)| &= \frac{1}{2}(x - x^*)^\top A_\alpha (x - x^*) + (x^*)^\top A_\alpha (x - x^*) + a_\alpha^\top (x - x^*) \\ &= \frac{1}{2}(x - x^*)^\top A_\alpha (x - x^*) + (\nabla h_\alpha(x^*))^\top (x - x^*). \end{aligned}$$

Define $\mu_0 = \lambda_{\min}(A_\alpha)$. Then

$$\begin{aligned} &\|\nabla h_\alpha(x)\|^2 - 2\mu_0|H(x) - H(x^*)| \\ &= (x - x^*)^\top A_\alpha (A_\alpha - \mu_0 I)(x - x^*) + \|\nabla h_\alpha(x^*)\|^2 \\ &\quad + 2(\nabla h_\alpha(x^*))^\top (A_\alpha - \mu_0 I)(x - x^*) \\ &= \|(A_\alpha - \mu_0 I)(x - x^*) + \nabla h_\alpha(x^*)\|^2 + \mu_0(x - x^*)^\top (A_\alpha - \mu_0 I)(x - x^*) \geq 0. \end{aligned}$$

Also note that μ_0 is bounded from below because $\alpha A_1 + (1-\alpha)A_2 \succ 0$ for α in the compact interval $[\frac{\alpha_0}{4}, 1 - \frac{1-\alpha_0}{4}]$. Let $C_2 = \sqrt{1/(2\mu_0)}$. We have

$$C_2 \|\nabla h_\alpha(x)\| \geq |H(x) - H(x^*)|^{1/2}, \quad \forall \alpha \in [\frac{\alpha_0}{4}, 1 - \frac{1-\alpha_0}{4}], \quad x \in \mathcal{B}(x^*, \epsilon_4).$$

Combining cases (a) and (b) gives rise to

$$|H(x) - H(x^*)|^{1/2} \leq C_3 \|\nabla h_\alpha(x)\|$$

with $C_3 = \max\{C_1, C_2\}$, for all $x \in \mathcal{B}(x^*, \epsilon_4)$.

Combining cases 1 and 2 yields that the KL inequality (7) holds with $C = \max\{C_0, C_3\}$ for all $x \in \mathcal{B}(x^*, \epsilon)$ with $\epsilon = \max\{\epsilon_0, \epsilon_4\}$. \square

Note that the assumption of $\min h_1(x) < \min H(x)$ and $\min h_2(x) < \min H(x)$ means that we are in the easy case of GTRS as in this case λ^* is an interior point of I_{PSD} and $Q_1 + \lambda^* Q_2$ is nonsingular, where λ^* is the optimal Lagrangian multiplier of the GTRS [36]. However, there are two situations for the hard case. Let us consider the KL property for $H(x)$ at the optimal solution x^* . When $h_i(x^*) > h_j(x^*)$, for $i = 1$ or 2 and $j = \{1, 2\} \setminus \{i\}$, in the neighbourhood x^* , $H(x)$ is just $h_i(x)$ (a convex quadratic function), and the KL is also $1/2$ [6]. In such a case, our algorithm performs asymptotically like the gradient descent method for unconstrained quadratic minimization. However, when $h_i(x^*) = h_j(x^*)$ (note that $\min h_j(x) < H(x^*)$ can still hold in this situation), the KL exponent is not always $1/2$ for $H(x)$. Consider the following counterexample with $h_1(x) = x_1^2$ and $h_2(x) = (x_1 + 1)^2 + x_2^2 - 1$. The optimal solution is $(0, 0)$ and is attained by both h_1 and h_2 . Let $x_2 = -\epsilon$, where ϵ is a small positive number. Consider the curve where $h_1(x) = h_2(x)$, which further implies $x_1 = -\epsilon^2/2$. Then we have

$$(1 - \beta)\nabla h_1 + \beta\nabla h_2 = 2 \begin{pmatrix} -(1 - \beta)\frac{\epsilon^2}{2} + \beta(-\frac{\epsilon^2}{2} + 1) \\ -\beta\epsilon \end{pmatrix} = 2 \begin{pmatrix} -\frac{\epsilon^2}{2} + \beta \\ -\beta\epsilon \end{pmatrix},$$

and thus

$$\begin{aligned}
 \min_{y \in \partial H(x)} \|y\|^2 &= \min_{\beta} 4 \left(\beta^2 \epsilon^2 + \beta^2 - \epsilon^2 \beta + \frac{\epsilon^4}{4} \right) \\
 &= \min_{\beta} 4 \left((1 + \epsilon^2) \left(\beta - \frac{\epsilon^2}{2(1 + \epsilon^2)} \right)^2 - \frac{\epsilon^4}{4(1 + \epsilon^2)} + \frac{\epsilon^4}{4} \right) \\
 &= \frac{\epsilon^6}{(1 + \epsilon^2)} = \epsilon^6 + O(\epsilon^8).
 \end{aligned}$$

Thus, $\min_{y \in \partial H(x)} \|y\| = O(\epsilon^3)$. On the other hand,

$$H(x) - H(x^*) = x_1^2 = \frac{\epsilon^4}{4}.$$

Hence the KL inequality cannot hold with $\theta = 1/2$. However, the KL exponent is $\theta = 3/4$ because that $\theta = 3/4$ if $h_1(x) = h_2(x)$ and that when $h_1(x) \neq h_2(x)$, $\theta = 1/2$ holds for the same reason to unconstrained convex quadratic minimization [32] if h_1 is active and for the same reason as in Case 1 in proof in Theorem 3.4 if h_2 is active.

An anonymous referee points out that the results in Theorem 3.4 can also be deduced directly from existing results in [47, Theorem 3.1] and [11, Theorem 5]: Let H^* be the optimal value of problem (M). Then consider the system

$$h_1(x) - H^* \leq 0, \quad h_2(x) - H^* \leq 0.$$

[47, Theorem 3.1] states that a growth condition holds locally (note that the degree of singularity of the system $d = 1$ and locally the term in [47, Theorem 3.1] with exponent $1/2$ is dominant). Combining this with [11, Theorem 5] gives a KL exponent of $1/2$. Moreover, one can further demonstrate that the KL exponent would be $3/4$ as the degree of the singularity of the system will be 2 (e.g., the example in the above paragraph) when our assumption in Theorem 3.4 fails. So the KL exponent in general should be $3/4$. We should point out that our proof in Theorem 3.4 is derived in an independent way and also gives an explicit constant C (which can be found in the proof of Theorem 3.4).

For convergence analysis with error bounds or the KL property, we still need a sufficient descent property to achieve the convergence rate. We next propose an algorithm with such a property. We further show that our algorithm converges locally linearly with the descent direction chosen in Theorem 3.1 and the step size specified in the following theorem.

Theorem 3.5. *Assume that the conditions in Theorem 3.4 hold and that the initial point $x^0 \in \mathcal{B}(x^*, \epsilon)$. Assume that h_i is the active function when $h_1(x_k) \neq h_2(x_k)$ and h_j , $j = \{1, 2\} \setminus \{i\}$, is thus inactive. Let the descent direction be chosen in Theorem 3.1 and the associated step size be chosen as follows.*

1. When $h_1(x_k) = h_2(x_k)$,
 - if there exists $g_\alpha = \alpha \nabla h_1(x_k) + (1 - \alpha) \nabla h_2(x_k)$ with $\alpha \in [0, 1]$ such that $\nabla h_1(x_k)^\top g_\alpha = \nabla h_2(x_k)^\top g_\alpha$, then set $d_k = -g_\alpha$ and $\beta_k = 1/L$, where $L = \max\{\lambda_{\max}(A_1), \lambda_{\max}(A_2)\}$;
 - otherwise set $d_k = -\nabla h_i(x_k)$ for i such that $\nabla h_1(x_k)^\top \nabla h_2(x_k) > \nabla h_i(x_k)^\top \nabla h_i(x_k)$, $i = 1, 2$, and $\beta_k = 1/L$.
2. When $h_1(x_k) \neq h_2(x_k)$ and the following quadratic equation for γ ,

$$\mathbf{a}\gamma^2 + \mathbf{b}\gamma + \mathbf{c} = 0, \tag{8}$$

where $\mathbf{a} = \frac{1}{2} \nabla h_i(x_k)^\top (A_i - A_j) \nabla h_i(x_k)$, $\mathbf{b} = (\nabla h_i(x_k)^\top - \nabla h_j(x_k)^\top) \nabla h_i(x_k)$ and $\mathbf{c} = h_i(x_k) - h_j(x_k)$, has no positive solution or all positive solutions of (8) satisfy $\gamma \geq 1/L$, set $d_k = -\nabla h_i(x_k)$ with and $\beta_k = 1/L$;

3. When $h_1(x_k) \neq h_2(x_k)$ and the quadratic equation (8) has a positive solution $\gamma < 1/L$, set $\beta_k = \gamma$ and $d_k = -\nabla h_i(x_k)$.

Then the sequence $\{x_k\}$ generated by Algorithm 1 satisfies, for any $k \geq 1$,

$$H(x_k) - H(x^*) \leq \left(\sqrt{\frac{2C^2L - 1}{2C^2L}} \right)^{k-1} (H(x^0) - H(x^*)), \quad (9)$$

and

$$\text{dist}(x_k, \bar{X})^2 \leq \frac{2}{L} (H(x_k) - H(x^*)) \leq \frac{2}{L} \left(\sqrt{\frac{2C^2L - 1}{2C^2L}} \right)^{k-1} (H(x^0) - H(x^*)),$$

where C is the same constant in (7).

Before going to the proof of the above theorem, we provide some intuition how to choose the step size in the following remark.

Remark 3.6. We here give some intuition for the quadratic equation (8). This equation is mainly to detect whether h_i is still active at iteration $k + 1$. In fact, the left hand side of the equation is just

$$\frac{1}{2} \nabla h_i(x_k)^\top (A_i - A_j) \nabla h_i(x_k) \gamma^2 + (\nabla h_i(x_k)^\top - \nabla h_j(x_k)^\top) \nabla h_i(x_k) \gamma + h_i(x_k) - h_j(x_k),$$

and is further equivalent to

$$h_i(x_k + \gamma \nabla h_i(x_k)) - h_j(x_k + \gamma \nabla h_i(x_k)).$$

First note that we assumed that h_i is active at iteration k , i.e., $h_i(x_k) - h_j(x_k) > 0$. Note also that the quadratic function in LHS of equation (8) is still nonnegative, i.e., h_i is still active at iteration $k + 1$, for step size less than or equal to $1/L$, if the equation (8) has no positive solution, or all positive solutions of (8) satisfy $\gamma \geq 1/L$ (Step 2). Hence with the step size $1/L$, h_i is still active at iteration $k + 1$ in Step 2. And when the equation (8) has a positive solution $\gamma < 1/L$, setting $\beta_k = \gamma$ and $d_k = -\nabla h_i(x_k)$ makes $h_1(x_k + \beta_k d_k) = h_2(x_k + \beta_k d_k)$ (Step 3). As $h_1(x_{k+1}) = h_2(x_{k+1})$ after every Step 3, we must have Step 1 at the $(k + 1)$ th iteration. The main purpose of introducing Step 3 is to make sure that (11) (in the proof) holds for more than half steps (this is true for our algorithm as Step 3 is followed by Step 1) to guarantee the convergence rate. The reason of this step is that the second equality in (11) may fail as the step size may be tiny and instead we have $H(x_l) - H(x^*) \leq \frac{2C^2}{L\gamma^2} (H(x_l) - H(x_{l+1}))$, which is equivalent to $H(x_{l+1}) - H(x^*) \leq \frac{2C^2 - L\gamma^2}{2C^2} (H(x_l) - H(x^*))$, and thus the function value decrease in Step 3 may be very tiny because γ may be very close to 0.

It is worth to note that Step 3 in the above theorem is somehow similar to the retraction step in manifold optimization [3]. In manifold optimization, in every iteration, each point is retracted to the manifold. In Step 3, every point is drawn to the curve that $h_1(x) = h_2(x)$.

We next give a proof for Theorem 3.5.

Proof. For simplicity, let us denote $g_i = \nabla h_i(x_k)$ for $i = 1, 2$. We claim the following sufficient descent property for steps 1, 2 and 3:

$$H(x_k) - H(x_{k+1}) \geq \frac{L}{2} \|x_k - x_{k+1}\|^2. \quad (10)$$

Hence, if the step size is $1/L$ (i.e., steps 1 and 2), we have

$$H(x_l) - H(x^*) \leq C^2 \|d_l\|^2 = C^2 L^2 \|x_l - x_{l+1}\|^2 \leq 2C^2 L (H(x_l) - H(x_{l+1})), \quad (11)$$

where the first inequality is due to the KL inequality in Theorem 3.4, the second equality is due to $x_{l+1} = x_l - \frac{1}{L}d_l$ and the last inequality is due to the sufficient descent property. Rearranging the above inequality yields

$$H(x_{l+1}) - H(x^*) \leq \frac{2C^2L - 1}{2C^2L} (H(x_l) - H(x^*)).$$

And due to (10), we have $H(x_{l+1}) - H(x^*) \leq H(x_l) - H(x^*)$ for all iterations. Suppose that there are p iterates of Step 1, q iterates of Step 2, and r iterates of Step 3. From the definitions of the steps, every Step 3 is followed by a Step 1 if we terminate our algorithm at Step 1 or 2 and thus $r \leq p + 1$. So for all $k \geq 1$, after $k = p + q + r$ steps, we have

$$H(x_k) - H(x^*) \leq \left(\frac{2C^2L - 1}{2C^2L} \right)^{p+q} (H(x^0) - H(x^*)) \leq \left(\frac{2C^2L - 1}{2C^2L} \right)^{\frac{k-1}{2}} (H(x^0) - H(x^*)).$$

The sufficient descent property further implies that

$$\frac{L}{2} \sum_{i=k}^{\infty} \|x_i - x_{i+1}\|^2 \leq H(x_k) - H(x^*).$$

Hence, with $\sum_{i=k}^{\infty} \|x_i - x_{i+1}\|^2 \geq \text{dist}(x_k, \bar{X})^2$, we have $\frac{L}{2} \text{dist}(x_k, \bar{X})^2 \leq H(x_k) - H(x^*)$. Thus,

$$\text{dist}(x_k, \bar{X})^2 \leq \frac{2}{L} (H(x_k) - H(x^*)).$$

By noting $g_i = A_i x_k + a_i$, for any $u \in \mathbb{R}^n$ we have

$$h_i(x_k + u) - h_i(x_k) = \frac{1}{2} u^\top A_i u + g_i^\top u,$$

which will be used several times in the latter proof. We next prove our claim of sufficient descent property (10) according to the three cases in our updating rule:

1. When $h_1(x_k) = h_2(x_k)$, assuming that h_m , $m \in \{1, 2\}$, is active at x_{k+1} , we have

$$H(x_k) - H(x_{k+1}) = h_m(x_k) - h_m(x_{k+1}).$$

- If there exists an α such that $g_\alpha^\top g_1 = g_\alpha^\top g_2$, we have $g_\alpha^\top g_j = g_\alpha^\top g_\alpha$. And by noting that $d_k = -g_\alpha$ and that the step size is $1/L$, we further have

$$\begin{aligned} h_m(x_{k+1}) - h_m(x_k) &= \frac{1}{2L^2} d_k^\top A_m d_k + \frac{1}{L} g_m^\top d_k \\ &\leq \frac{1}{2L} g_\alpha^\top g_\alpha - \frac{1}{L} g_\alpha^\top g_\alpha \\ &= -\frac{1}{2L} g_\alpha^\top g_\alpha, \end{aligned}$$

where the first inequality follows because $\lambda_{\max}(A_m) \leq L$ and $g_\alpha^\top g_m = g_\alpha^\top g_\alpha$. Substituting $g_\alpha = L(x_k - x_{k+1})$ to the above expression, we have the following sufficient descent property,

$$H(x_k) - H(x_{k+1}) = h_m(x_k) - h_m(x_{k+1}) \geq \frac{L}{2} \|x_k - x_{k+1}\|^2.$$

- If there does not exist an $\alpha \in [0, 1]$ such that $g_\alpha^\top g_1 = g_\alpha^\top g_2$, then we must have $\alpha g_1^\top g_1 + (1 - \alpha) g_2^\top g_1 > \alpha g_1^\top g_2 + (1 - \alpha) g_2^\top g_2$ for all $\alpha \in [0, 1]$ or $\alpha g_1^\top g_1 + (1 - \alpha) g_2^\top g_1 < \alpha g_1^\top g_2 + (1 - \alpha) g_2^\top g_2$ for all $\alpha \in [0, 1]$. As the above relation is linear, the inequality holds if and only if it holds at the end

point $\alpha = 0$ and $\alpha = 1$. And thus we must have $g_1^\top g_1 > g_1^\top g_2 > g_2^\top g_2$ or $g_2^\top g_2 > g_1^\top g_2 > g_1^\top g_1$. If $g_i^\top g_i > g_i^\top g_j > g_j^\top g_j$, we set $d_k = -g_j$. Then

$$\begin{aligned} H(x_{k+1}) - H(x_k) &\leq \max\{h_i(x_{k+1}) - h_i(x_k), h_j(x_{k+1}) - h_j(x_k)\} \\ &\leq \max\left\{\frac{1}{2L^2}g_j^\top A_i g_j - \frac{1}{L}g_i^\top g_j, \frac{1}{2L^2}g_j^\top A_j g_j - \frac{1}{L}g_j^\top g_j\right\} \\ &\leq \max\left\{\frac{1}{2L^2}g_j^\top A_i g_j - \frac{1}{L}g_j^\top g_j, \frac{1}{2L^2}g_j^\top A_j g_j - \frac{1}{L}g_j^\top g_j\right\} \\ &\leq \max\left\{\frac{1}{2L}g_j^\top g_j - \frac{1}{L}g_j^\top g_j, \frac{1}{2L}g_j^\top g_j - \frac{1}{L}g_j^\top g_j\right\} \\ &= -\frac{1}{2L}g_j^\top g_j = -\frac{L}{2}\|x_k - x_{k+1}\|^2. \end{aligned}$$

Symmetrically, if $g_j^\top g_j > g_i^\top g_j > g_i^\top g_i$, setting $d_k = -g_i$ yields the same sufficient descent property.

2. When $h_1(x_k) \neq h_2(x_k)$ and the quadratic equation (8) for γ has no positive solution or all its positive solutions $\gamma \geq 1/L$, we have $h_i(x_{k+1}) > h_j(x_{k+1})$ for $x_{k+1} = x_k + \beta_k d_k$, where $d_k = -\nabla h_i(x_k)$ and $\beta_k = \frac{1}{L}$. Moreover,

$$\begin{aligned} H(x_{k+1}) - H(x_k) &= h_i(x_{k+1}) - h_i(x_k) \\ &= \frac{1}{2L^2}g_i^\top A_i g_i - \frac{1}{L}g_i^\top g_i \\ &\leq -\frac{1}{2L}g_i^\top g_i. \end{aligned}$$

Hence $H(x_k) - H(x_{k+1}) \geq \frac{1}{2L}g_i^\top g_i \geq \frac{L}{2}\|x_k - x_{k+1}\|^2$.

3. When $h_1(x_k) \neq h_2(x_k)$ and the quadratic equation (8) has a positive solution $\gamma < 1/L$. With $\beta_k = \gamma$ and $d_k = -\nabla h_i(x_k)$, from the definition of γ , we see that the step size γ makes $h_1(x_{k+1}) = h_2(x_{k+1})$. Then we have

$$\begin{aligned} H(x_{k+1}) - H(x_k) &= h_i(x_{k+1}) - h_i(x_k) \\ &= \frac{1}{2}\gamma^2 d_k^\top A_i d_k + \gamma g_i^\top d_k \\ &\leq \frac{1}{2}L\gamma^2 g_i^\top g_i - \gamma g_i^\top g_i \\ &= \left(\frac{L}{2} - \frac{1}{\gamma}\right)\|x_k - x_{k+1}\|^2, \end{aligned}$$

which further implies $H(x_k) - H(x_{k+1}) \geq \frac{L}{2}\|x_k - x_{k+1}\|^2$ due to $\gamma \leq \frac{1}{L}$.

□

We will next show that in general a global sublinear convergence rate, in the same order with the gradient descent algorithm, can also be theoretically guaranteed for Algorithm 1.

Theorem 3.7. *Assume that x^* is an optimal solution and x_0 is an arbitrary initial point. Then we have*

$$H(x_N) - H(x^*) \leq \frac{L}{N}\|x_0 - x^*\|^2.$$

That is, the required iterate number for $H(x_N) - H(x^) \leq \epsilon$ is at most $O(1/\epsilon)$.*

Proof. From the proof in Theorem 3.5, for any step size $\gamma \leq 1/L$, we have

$$H(x_{k+1}) - H(x_k) \leq -\gamma g^\top g + \frac{1}{2}L\gamma^2 g^\top g \leq -\frac{\gamma}{2}g^\top g.$$

From the convexity of $H(x)$ and $g \in \partial H(x_k)$, we have

$$\begin{aligned} H(x_{k+1}) &\leq H(x_k) - \frac{\gamma}{2}g^\top g \\ &\leq H(x^*) + g^\top(x_k - x^*) - \frac{\gamma}{2}g^\top g \\ &= H(x^*) + \frac{1}{2\gamma} \left(\|x_k - x^*\|^2 - \|x_k - x^* - \gamma g\|^2 \right) \\ &= H(x^*) + \frac{1}{2\gamma} \left(\|x_k - x^*\|^2 - \|x_{k+1} - x^*\|^2 \right). \end{aligned}$$

Since $H(x_{k+1}) \geq H(x^*)$, we have

$$\|x_k - x^*\|^2 - \|x_{k+1} - x^*\|^2 \geq 0. \quad (12)$$

Let us use indices i_k , $k = 0, \dots, K$ to denote the indices in Steps 1 and 2. By noting that $\gamma = 1/L$, we have

$$H(x_{i_{k+1}}) \leq H(x^*) + \frac{L}{2} \left(\|x_{i_k} - x^*\|^2 - \|x_{i_{k+1}} - x^*\|^2 \right).$$

Note that every Step 3 is followed by Step 1. Hence $N \leq 2K + 1$. Adding the above inequalities from i_0 to i_K , we have

$$\begin{aligned} &\sum_{k=0}^K H(x_{i_k}) - H(x^*) \\ &\leq \frac{L}{2} \sum_{k=0}^K \left(\|x_{i_k} - x^*\|^2 - \|x_{i_{k+1}} - x^*\|^2 \right) \\ &= \frac{L}{2} \left(\|x_{i_0} - x^*\|^2 - \|x_{i_{K+1}} - x^*\|^2 + \sum_{k=1}^K \left(-\|x_{i_{k-1}+1} - x^*\|^2 + \|x_{i_k} - x^*\|^2 \right) \right) \\ &\leq \frac{L}{2} (\|x_{i_0} - x^*\|^2 - \|x_{i_{K+1}} - x^*\|^2) \\ &\leq \frac{L}{2} \|x_{i_0} - x^*\|^2 \\ &\leq \frac{L}{2} \|x_0 - x^*\|^2, \end{aligned}$$

where the second inequality is due to (12) and $i_{k-1} < i_k$. Since $H(x_k)$ is non-increasing, by noting that $N \leq 2K + 1$, we have

$$H(x_N) - H(x^*) \leq \frac{1}{K+1} \sum_{k=0}^K H(x_{i_k}) - H(x^*) \leq \frac{L}{N} \|x_0 - x^*\|^2.$$

13:  Choose a step size  $\beta_k > 0$  according to the modified Armijo rule (13)
14:  Update  $x_{k+1} = x_k + \beta_k d_k$ 
15: end for
    
```

3.2 Line search with a modified Armijo rule

An alternative way to choose the step size in the classical gradient descent type methods is a line search with the Armijo rule. A natural thought is then to extend the Armijo rule in our minimax problem (M) as in the proposed Algorithm 2. In particular, we set the following modified Armijo rule to choose the smallest nonnegative integer t such that the following inequality holds for the step size $\beta_k = \xi s^t$ with $0 < \xi \leq 1$ and $0 < s < 1$,

$$f(x_k + \beta_k p_k) \leq f(x_k) - \sigma \beta_k p_k^\top d_k, \quad (13)$$

where $0 \leq \sigma \leq 0.5$ and d_k is the steepest descent direction defined in Line 8 in Algorithm 2, which is similar to the steepest descent direction in Algorithm 1. Particularly, we set the search direction $p_k = d_k$ at iterate k . Our numerical result in the next section shows that Algorithm 2 has a comparable performance when compared with (or even better than) Algorithm 1. For the sake of completeness, we present the convergence result for Algorithm 2 in the following. Before that, we generalize the definition of a critical point to a (ρ, δ) critical point.

Definition 3.8. A point x is called a (ρ, δ) critical point of $H(x) = \max\{h_1(x), h_2(x)\}$ if $\exists \|g\| < \delta$, for some $g \in \partial H_\rho(x)$, where $\partial H_\rho(x)$ is defined as follows:

1. $\partial H_\rho(x) = \{\alpha \nabla h_1(x) + (1 - \alpha) \nabla h_2(x) : \alpha \in [0, 1]\}$, if $|h_1(x) - h_2(x)| \leq \rho$;
2. $\partial H_\rho(x) = \{\nabla h_1(x)\}$, if $h_1(x) - h_2(x) > \rho$; or
3. $\partial H_\rho(x) = \{\nabla h_2(x)\}$, if $h_2(x) - h_1(x) > \rho$.

The following proposition shows the relationship of a critical point and a (ρ, δ) critical point. As this result is pretty obvious, we omit its proof.

Proposition 3.9. *Assume that $\{x_k\}$ is a sequence in \mathbb{R}^n and that $(\rho^t, \delta^t) \rightarrow (0, 0)$, for $t \rightarrow \infty$ and that there exists a positive integer $K(t)$, such that x_k is a (ρ^t, δ^t) critical point of $H(x)$ for all $k \geq K(t)$ and $t \geq 1$. Then, every accumulation point of the sequence $\{x_k\}$ is a critical point of $H(x)$.*

Slightly different from Algorithm 1, our goal in Algorithm 2 is to find a (ρ, δ) critical point. With Proposition 3.9, we conclude that Algorithm 2 outputs a solution that is sufficiently close to a critical point of $H(x)$.

Theorem 3.10. *Assume that i) $d = -\operatorname{argmin}_{y \in \partial H_\rho(x_k)} \|y\|$ with $\rho > 0$, ii) the termination criterion is $\|d\| < \delta$ for some $\delta > 0$ and iii) x^* is an optimal solution. Then the line search procedure in Algorithm 2 is well-defined, i.e., the step size β_k is bounded from below in each iteration. And for any given positive numbers ρ and δ , Algorithm 2 generates a (ρ, δ) critical point in at most*

$$\frac{H(x_0) - H(x^*)}{\sigma s \min\{1/L, \xi, \frac{\rho}{2G^2}\} \delta^2}$$

iterations, where G is some positive constant only depending on the initial point and problem setting.

Proof. Suppose at iteration 1 to k , we have $\|d\| \geq \delta$. Consider the following different cases with $\|d\| \geq \delta$.

1. If $|h_1(x_k) - h_2(x_k)| \leq \rho$, then as assumed $\|d\| \geq \delta$ and from the the proof of Theorem 3.1, we know that $d = -(\alpha \nabla h_1(x_k) + (1 - \alpha) \nabla h_2(x_k))$, where

$$\alpha = \operatorname{argmin}_{\alpha \in [0, 1]} \|\alpha \nabla h_1(x_k) + (1 - \alpha) \nabla h_2(x_k)\|$$

is just the parameter α we choose in Algorithm 2. We next show that the step size β_k is bounded from below such that

$$H(x_{k+1}) - H(x_k) \leq -\sigma \beta_k d^\top d.$$

Since

$$\begin{aligned} H(x_{k+1}) - H(x_k) &= \max\{h_1(x_{k+1}), h_2(x_{k+1})\} - \max\{h_1(x_k), h_2(x_k)\} \\ &\leq \max\{h_1(x_{k+1}) - h_1(x_k), h_2(x_{k+1}) - h_2(x_k)\}, \end{aligned}$$

it suffices to show that β_k is bounded from below such that for both $i = 1$ and 2 ,

$$h_i(x_{k+1}) - h_i(x_k) = \beta_k \nabla h_i(x_k)^\top d + \frac{1}{2} \beta_k^2 d^\top A_i d \leq -\sigma \beta_k d^\top d. \quad (14)$$

By noting that $-\nabla h_i^\top d \geq d^\top d$ from Remark 3.2 and $\lambda_{\max}(A_i) \leq L$, $i = 1$ or 2 , the second inequality in (14) holds true for all $\beta_k \leq 2(1 - \sigma)/L$. Then due to (14), the step size chosen by the modified Armijo rule satisfies $\beta_k \geq s \min\{2(1 - \sigma)/L, \xi\}$ since if $\xi > 2(1 - \sigma)/L$ there exists an integer t such that $2s(1 - \sigma)/L \leq \xi s^t \leq 2(1 - \sigma)/L$ and if $\xi \leq 2(1 - \sigma)/L$, the Armijo condition holds at $t = 0$. That is, β_k must be lower bounded. This further implies that

$$H(x_k) - H(x_{k+1}) \geq \sigma \beta_k d^\top d \geq \sigma s \min\{2(1 - \sigma)/L, \xi\} \delta^2.$$

2. If $h_1(x_k) - h_2(x_k) > \rho$ and $\|\nabla h_1(x_k)\| \geq \delta$, we have $d = -\nabla h_1(x_k)$. Because $H(x_k)$ is decreasing, under Condition 2.6, $h_1(x_k) + h_2(x_k) = \frac{1}{2} x_k^\top (A_1 + A_2) x_k + (a_1 + a_2)^\top x_k + r_1 + r_2 \leq 2h_1(x_k) = 2H(x_k) \leq 2H(x_0)$ and thus x_k is bounded due to $A_1 + A_2 = 2(Q_1 + \frac{\lambda_1 + \lambda_2}{2} Q_2) \succ 0$. This further implies that $\nabla h_i(x_k) = A_i x_k + b_i$, $i = 1$ or 2 , is bounded for all k . So there exists some positive constant only depending on the initial point and problem parameters such that $\|\nabla h_i(x_k)\| \leq G$, $i = 1$ or 2 . Hence $\|d\| \leq G$ because d is just $-\nabla h_1(x_k)$. Then we have, for any $\beta_k \leq 1/L$,

$$h_1(x_{k+1}) - h_1(x_k) \leq \beta_k \nabla h_1(x_k)^\top d + \frac{1}{2} \beta_k^2 d^\top A_1 d \leq -\beta_k d^\top d + \frac{1}{2} \beta_k^2 L d^\top d \leq -\frac{1}{2} \beta_k d^\top d$$

and

$$\begin{aligned}
 h_2(x_{k+1}) - h_2(x_k) &\leq \beta_k \nabla h_2(x_k)^\top d + \frac{1}{2} \beta_k^2 d^\top A_i d \\
 &\leq \beta_k G \|d\| + \frac{1}{2} \beta_k^2 L \|d\|^2 \\
 &\leq \beta_k G^2 (1 + \frac{1}{2} \beta_k L) \\
 &\leq \frac{3}{2} \beta_k G^2.
 \end{aligned}$$

Note that for all $\beta_k \leq \frac{\rho}{2G^2}$, $\frac{3}{2} \beta_k G^2 + \frac{1}{2} \beta_k d^\top d \leq \rho$. Thus for $\beta_k \leq \min\{1/L, \frac{\rho}{2G^2}\}$, we have

$$\begin{aligned}
 h_1(x_{k+1}) &\leq h_1(x_k) - \frac{1}{2} \beta_k d^\top d, \\
 h_2(x_{k+1}) &\leq h_2(x_k) + \frac{3}{2} \beta_k G^2 \leq h_1(x_k) - \rho + \frac{3}{2} \beta_k G^2 \leq h_1(x_k) - \frac{1}{2} \beta_k d^\top d.
 \end{aligned}$$

Hence, for $\beta_k \leq \min\{1/L, \frac{\rho}{2G^2}\}$, we have

$$\begin{aligned}
 H(x_{k+1}) - H(x_k) &= \max\{h_1(x_{k+1}), h_2(x_{k+1})\} - h_1(x_k) \\
 &= \max\{h_1(x_{k+1}) - h_1(x_k), h_2(x_{k+1}) - h_1(x_k)\} \\
 &\leq -\frac{1}{2} \beta_k d^\top d.
 \end{aligned}$$

So the Armijo rule implies $\beta_k \geq s \min\{1/L, \xi, \frac{\rho}{2G^2}\}$ due to a similar reason to the previous case. This is, β_k is lower bounded. Then according to the modified Armijo rule, we have

$$H(x_k) - H(x_{k+1}) \geq \sigma \beta_k d^\top d \geq \sigma s \min\{1/L, \xi, \frac{\rho}{2G^2}\} \delta^2. \quad (15)$$

3. Symmetrically, the case with $h_2(x_k) - h_1(x_k) > \rho$ yields the same result as in (15).

The above three cases show that $H(x_k) - H(x_{k+1}) \geq \sigma s \min\{1/L, \xi, \frac{\rho}{2G^2}\} \delta^2$ (as $1 - \sigma \geq 1/2$, the decrease in case 1 also admits this bound). Since the decrease in each iterate is larger than $\sigma s \min\{1/L, \xi, \frac{\rho}{2G^2}\} \delta^2$, the total iterate number is bounded by

$$\frac{H(x_0) - H(x^*)}{\sigma s \min\{1/L, \xi, \frac{\rho}{2G^2}\} \delta^2}.$$

□

At the current stage, we cannot demonstrate a theoretical convergence rate for Algorithm 2 as good as the sublinear rate $O(1/\rho)$ for Algorithm 1 in Theorem 3.7. But our numerical tests show that Algorithm 2 converges as fast as Algorithm 1. Proposition 3.9 and Theorem 3.10 offer our main convergence result for Algorithm 2 as follows.

Theorem 3.11. *Assume that $(\phi_k, \psi_k) \rightarrow 0$ and that $\{x^{(k)}\}$ is a sequence of solutions generated by Algorithm 2 with $\rho = \phi_k$ and $\delta = \psi_k$. Then any accumulation point of $\{x^{(k)}\}$ is an optimal solution of problem (M).*

4 Numerical tests

In this section, we illustrate the efficiency of our algorithm with numerical experiments. All the numerical tests were implemented in Matlab 2016a, 64bit and were run on a Linux machine with 48GB RAM, 2600MHz cpu and 64-bit CentOS release 7.1.1503. We compare both Algorithms 1 and 2 with the ERW algorithm in [40]. We disable the parallel setting in the Matlab for fair comparison. If the parallel setting is allowed, our algorithm has a significant improvement, while the ERW algorithm does not.

We use the following same test problem as in [40] to show the efficiency of our algorithms,

$$\begin{aligned} (\text{IP}) \quad & \min \quad x^\top Ax - 2a^\top x \\ & \text{s.t.} \quad c_1 \leq x^\top Bx \leq c_2, \end{aligned}$$

where A is an $n \times n$ positive definite matrix and B is an $n \times n$ (nonsingular) symmetric indefinite matrix. We first reformulate problem (IP) to a formulation of problem (P) in the following procedure, which is motivated from [40] (the proof in [40] is also based on the monotonicity of $\gamma(\lambda)$, which is defined in Section 2.1), in order to apply the CQR for problem (P) and then invoke Algorithms 1 and 2 to solve the CQR.

Theorem 4.1. *Let $x_0 = -A^{-1}a$. Then the followings hold.*

1. *If $x_0^\top Bx_0 < c_1$, problem (IP) is equivalent to*

$$(\text{IP}_1) \quad \min\{x^\top Ax - 2a^\top x : \text{s.t. } c_1 \leq x^\top Bx\};$$

2. *Else if $c_1 \leq x_0^\top Bx_0 \leq c_2$, problem (IP) admits an interior solution x_0 ;*

3. *Otherwise $c_2 < x_0^\top Bx_0$, problem (IP) is equivalent to*

$$(\text{IP}_2) \quad \min\{x^\top Ax - 2a^\top x : \text{s.t. } x^\top Bx \leq c_2\}.$$

Proof. Item 2 is obvious. Item 1 and Item 3 are symmetric. So in the following, we only prove Item 1.

In our problem set, matrix A is positive definite and B is indefinite. Hence, in the definition $I_{PSD} = \{\lambda : Q_1 + \lambda Q_2 \succeq 0\}$, we have $\lambda_1 < 0$, $\lambda_2 > 0$. Thus from Case 1 in Section 2.2.2 in [40] we know, when $x_0^\top Bx_0 < c_1$, problem (IP) is equivalent to

$$(\text{EP}_1) \quad \min\{x^\top Ax - 2a^\top x : \text{s.t. } c_1 = x^\top Bx\}.$$

Since $x_0^\top Bx_0 < c_1$, the optimal solution of (IP_1) must be at its boundary [36]. This further yields the equivalence between problems (IP) and (IP_1) . \square

Theorem 4.1 helps us solve problem (IP) as an inequality constrained GTRS instead of solving two GTRS with equality constraints. Before showing the numerical results, let us illustrate some functions used in our initialization. To obtain the CQR, the generalized eigenvalue problem is solved by `eigfp` in Matlab, which was developed in [19] for computing the maximum generalized eigenvalues for sparse definite matrix pencils. In our numerical setting `eigfp` is usually faster than the Matlab function `eigs`, though `eigs` will outperform `eigfp` when the condition number is large or the density is low. We use the Matlab command `sprandsym(n,density,cond,2)` and `sprandsym(n,density)` to generate Q_1 and Q_2 . We set the density of matrices at 0.01 and use three levels of condition number for matrix Q_1 , i.e., 10, 100 and 1000 and, in such settings, `eigfp` always dominates `eigs` (this may be because `eigs` is developed for computing extreme generalized eigenvalues for arbitrary matrices and does not utilize the definiteness and symmetry properties of the matrix pencils in our problem setting). In general, the main cost in estimating L is to compute the maximum eigenvalues of matrices A_1 and A_2 , which may be time consuming for large-scale matrices. To conquer this difficulty, we can estimate a good upper bound with very cheap cost instead. Specially, we can run the function `eigfp` with precision 0.1, which is much

more efficient than computing the true maximum eigenvalue with `eigfp`, and, assuming M is the output, $M + 0.1$ is then a good upper bound for L . In our numerical tests, we just use `eigfp` to estimate L since our main goal is to illustrate the efficiency of Algorithm 2. In Algorithm 1, to avoid some numerical accuracy problem, we approximate $h_1(x_k) = h_2(x_k)$ by $|h_1(x_k) - h_2(x_k)|/(|h_1(x_k)| + |h_2(x_k)|) \leq \epsilon_1$. Also we use $|h_1(x_k) - h_2(x_k)|/(|h_1(x_k)| + |h_2(x_k)|) \leq \epsilon_1$ instead of $|h_1(x_k) - h_1(x_k)| \leq \rho$ in Algorithm 2 for stableness consideration. In our numerical tests for both Algorithms 1 and 2, we use the following termination criteria (if any one of the following three conditions is met, we terminate our algorithm), which are slightly different from the presented algorithms for robust consideration:

1. $H(x_{k-1}) - H(x_k) < \epsilon_2$,
2. $|h_1(x_k) - h_2(x_k)|/(|h_1(x_k)| + |h_2(x_k)|) \leq \epsilon_1$ and $\min_{\alpha \in [0,1]} \|\alpha \nabla h_1(x_k) + (1 - \alpha) \nabla h_2(x_k)\| \leq \epsilon_3$,
3. $\|\nabla h_i(x_k)\| \leq \epsilon_3$ and $|h_1(x_k) - h_2(x_k)|/(|h_1(x_k)| + |h_2(x_k)|) > \epsilon_1$ with $i \in \{1, 2\}$,

where ϵ_1 , ϵ_2 and $\epsilon_3 > 0$ are some small positive numbers for termination of the algorithm. Particularly, we set $\epsilon_1 = 10^{-8}$, $\epsilon_2 = 10^{-11}$ and $\epsilon_3 = 10^{-8}$ in Algorithm 1, and $\epsilon_1 = 10^{-8}$, $\epsilon_2 = 10^{-11}$, $\epsilon_3 = 10^{-8}$, $s = 0.5$, $\sigma = 10^{-4}$ and $\xi = 1$ (for the modified Armijo rule) in Algorithm 2.

To improve the accuracy of the solution, we apply the Newton refinement process in Section 4.1.2 in [5]. More specifically, assuming x^* is the solution returned by our algorithm, we update x^* by

$$\delta = \frac{(x^*)^\top B x^*}{2 \|B x^*\|^2} B x^*, \quad x^* = x^* - \delta.$$

In general, the ERW algorithm can achieve a higher precision than our method (after the Newton refinement process); the precision in their method is about 10^{-14} , while ours is slightly less precise than theirs. Letting v_1 denote the objective value of ERW algorithm and v_2 denote the objective value of our algorithm, we have at least $|v_2 - v_1|/|v_1| \approx 10^{-10}$ for most cases. The iteration number reduces to 1/5 if we reduce the precision of from $\epsilon_1 = 10^{-8}$, $\epsilon_2 = 10^{-11}$, $\epsilon_3 = 10^{-8}$ to $\epsilon_1 = 10^{-5}$, $\epsilon_2 = 10^{-8}$, $\epsilon_3 = 10^{-5}$. This observation seems reasonable as our method is just a first order method.

We report our numerical results in Table 1. We use “Alg1” and “Alg2” to denote Algorithms 1 and 2, respectively. For each n and each condition number, we generate 10 Easy Case and 10 Hard Case 1 examples. Please refer to Table 1 in [40] for the detailed definitions of Easy Case and Hard Cases 1 and 2. There is a little difference about the definitions of easy and hard cases between [40] and [36]. Our analysis in the above sections uses the definitions in [36]. In fact, the Easy Case and Hard Case 1 are the easy case and Hard Case 2 is the hard case mentioned in the above sections and [36]. We use the notation “time” to denote the average CPU time (in unit of second) and “iter” to denote the average iteration numbers for all the three algorithms. For “Alg1” and “Alg2”, “time” is just the time for

Algorithms 1 and 2, respectively. The notation “time_{eig}” denotes the average CPU time for computing the generalized eigenvalue for our algorithm. So the total time for solving problem (P) should be the summation of the time of reformulate (P) into (M) and the time of Algorithm 1 or 2, whose main cost is just “time” + “time_{eig}”. And “fail” denotes the failure times in the 10 examples in each case for the ERW algorithm. One reason of the failures may be that the ERW algorithm terminates in 10 iterations even when it does not find a good approximated solution. We point out that for randomly generated test examples, our method always succeeds in finding an approximated solution to prescribed precision while the ERW algorithm fails frequently in Hard Case 1. Another disadvantage of the ERW algorithm is the requirement of an efficient prior estimation of the initialization, which is unknown in general. In our numerical test, we assume that such an initialization is given as the same as [40] does.

We also need to point out that in the Hard Case 2, our algorithms do not outperform the ERW algorithm which uses the shift and deflation technique. The main time cost of shift and deflate operation is the computation of the extreme generalized eigenvalue of the matrix pencil (A, B) and its corresponding generalized eigenvectors. In the test instances, as the dimension of the eigenspace of the extreme generalized eigenvalue is one, the shift and deflation technique directly finds the optimal solution by calling `eigifp` once. Our algorithm reduces to an unconstrained quadratic minimization in Hard Case 2. However, the condition number of this unconstrained quadratic minimization is so large that our algorithm performs badly as the classical gradient method. To remedy this disadvantage, we can add a step with almost free-time cost that claims that either we are in Hard Case 2 and output an optimal solution or we are in Easy Case or Hard Case 1. Recall that the hard case (or equivalently, Hard Case 2) states that $b_1 + \lambda^* b_2$ is orthogonal to the null space of $Q_1 + \lambda^* Q_2$ which means that λ^* must be a boundary point of I_{PSD} . Suppose $\lambda_i = \lambda^*$. Then we must have that $x^* = \arg \min H(x)$ and $H(x^*) = h_i(x^*)$ for some $i=1$ or 2 . In fact, if $\nabla h_i(x) = 0$ and $h_i(x) \geq h_j(x)$, $j \in \{1, 2\}/\{i\}$ for some x , then x is optimal and we are in the hard case. So $\nabla h_i(x) = 0$ and $h_i(x) \geq h_j(x)$ is sufficient and necessary for x to be optimal to (M) and be in the hard case. Hence we can construct an optimal solution for problem (M) as $\bar{x} = (Q_1 + \lambda_i Q_2)^\dagger (b_1 + \lambda_i b_2) + \sum_{j=1}^k \alpha_j v_j$ (where A^\dagger denotes the *Moore–Penrose* pseudoinverse of A) if $v_j, j = 1, \dots, k$ are the generalized eigenvectors of matrix pencil (Q_1, Q_2) with respect to the generalized eigenvalue λ_i such that $h_i(\bar{x}) \geq h_j(\bar{x})$ and $\alpha \geq 0$. This equals to identifying if a small dimensional convex quadratic programming problem (with variable α) has an optimal value less than $h_i((Q_1 + \lambda_i Q_2)^\dagger (b_1 + \lambda_i b_2))$. And if such α does not exist, we are in the easy case (or equivalently, Easy Case or Hard Case 1). This technique is very similar to the shift and deflation technique in [17, 40]. Hence we can solve Hard Case 2 within almost the same CPU time as the ERW algorithm. So we do not make further comparison for Hard Case 2.

Our numerical tests show that both Algorithms 1 and 2 are much more efficient than the ERW algorithm in Easy Case and for most cases in Hard Case 1. The efficiency of our algorithms is mainly due to that we only call the generalized eigenvalue solver once and every iteration only involves several matrix vector products (which are very cheap for sparse matrices). We also note that, in Easy Case, Algorithm 1 is faster than Algorithm 2 when the condition number is small and slower than Algorithm 2 when the condition number is large. This may be because that Algorithm 2 is equipped with the modified Armijo rule, which makes it more aggressive in choosing the step size and thus yields a fast convergence. In Hard Case 1, Algorithm 2 is still much more efficient than the ERW algorithm while Algorithm 1 is slower than the ERW algorithm in about half the cases. This is because Algorithm 2 has a moderate iterate number due to the aggressiveness in choosing the step size and Algorithm 1 has a much large iterate number for these cases. Moreover, our algorithms always succeed, while the ERW algorithm fails frequently in Hard Case 1. A more detailed analysis with condition number for Algorithm 1 will be given in the following.

We note that several examples (of the 10 examples) in Easy Cases admit a much larger iteration number than average. This motivates us to analyze the main factor that affects the convergence rate (reflected by the iteration number) of Algorithm 1 (the analysis for Algorithm 2 seems hard due to the non-smoothness of the problem). We then find that the main factor is $\sqrt{\lambda_{\max} \alpha / 2 \lambda_{\min}^2 n n z \alpha}$, as evidenced by the fact that examples in Easy Case and Hard Case 1 with more iterates all have a larger $\sqrt{\lambda_{\max} \alpha / 2 \lambda_{\min}^2 n n z \alpha}$, where

$\lambda_{\max \alpha}$ denotes the maximum eigenvalue of matrix $\alpha A_1 + (1 - \alpha)A_2$ and $\lambda_{\min nnz\alpha}$ denotes the smallest nonzero eigenvalue of matrix $\alpha A_1 + (1 - \alpha)A_2$ with α being defined in Theorem 3.1 in the last iteration. In fact, when $x^k \rightarrow x^* \in \{x : \partial H(x) = 0\}$ (in our examples, the optimal solution is unique), let the value of α at iterate k be α^k , then $\alpha^k \rightarrow \alpha^*$, where α^* is the solution of $\alpha \nabla h_1(x^*) + (1 - \alpha) \nabla h_2(x^*) = 0$. From the definition of KL exponent, we have

$$C \times \min_{\alpha} \left\| \alpha \nabla h_1(x^k) + (1 - \alpha) \nabla h_2(x^k) \right\| \geq |H(x^k) - H(x^*)|^{1/2}.$$

Intuitively, the smallest value of C should be at least

$$\frac{|H(x^k) - H(x^*)|^{\frac{1}{2}}}{\min_{\alpha} \left\| \alpha \nabla h_1(x^k) + (1 - \alpha) \nabla h_2(x^k) \right\|} \rightarrow \frac{|\alpha(h_1(x^k) - h_2(x^*)) + (1 - \alpha)(h_1(x^k) - h_2(x^*))|^{\frac{1}{2}}}{\min_{\alpha} \left\| \alpha \nabla h_1(x^k) + (1 - \alpha) \nabla h_2(x^k) \right\|}$$

which is upper bounded by $\sqrt{\lambda_{\max \alpha} / 2\lambda_{\min nnz\alpha}^2}$. Thus, the asymptotic value of C can be roughly seen as $\sqrt{\lambda_{\max \alpha} / 2\lambda_{\min nnz\alpha}^2}$. Hence both Easy Case and Hard Case 1 admit local linear convergence and the convergence rate is

$$\left(\sqrt{1 - \frac{1}{2C^2L}} \right)^k = \left(\sqrt{1 - \frac{\lambda_{\min nnz\alpha}^2}{L\lambda_{\max \alpha}}} \right)^k$$

from Theorem 3.5. We also observe from our numerical tests that in most cases the values of $\lambda_{\max \alpha}$ are similar and that $\lambda_{\min nnz\alpha}$ in Easy Case is much larger than $\lambda_{\min nnz\alpha}$ in Hard Case 1 and $\lambda_{\max \alpha}$ in Easy Case is very close to $\lambda_{\max \alpha}$ in Hard Case 1. Hence, $\sqrt{1 - \lambda_{\min nnz\alpha}^2 / (L\lambda_{\max \alpha})}$ in Easy Case is usually much smaller than that in Hard Case 1. (As Q_2 is random in our setting, the larger the condition number of Q_1 is, the larger expectation of $\sqrt{1 - \lambda_{\min nnz\alpha}^2 / (L\lambda_{\max \alpha})}$ is.) This explains why the condition number of matrix Q_1 measures, to a large degree, the hardness of our algorithms in solving problem (M). Since Easy Case has a smaller $\sqrt{1 - (\lambda_{\min nnz\alpha}^2 / L\lambda_{\max \alpha})}$ than Hard Case 1 for the same condition number and problem dimension, Easy Case can be solved faster than Hard Case 1. This coincides with our numerical results, i.e., Easy Case admits a smaller iterate number than Hard Cases 1.

We also tried to apply MOSEK [2] to solve the CQR. But our numerical results showed that MOSEK is much slower than both our algorithms and the ERW algorithm, which took about 833 seconds for Easy Case and 960 second for Hard Case 1 with $n = 10000$ and $\text{cond} = 10$. So we do not run further numerical experiments with MOSEK. We also tested the SOCP reformulation [7] under the simultaneous digonalization condition of the quadratic forms of the GTRS and the DB algorithm in [42] based on the simultaneous digonalization condition of the quadratic forms. The simultaneous digonalization condition naturally holds for problem (IP) when A is positive definite. Our preliminary result shows that our method is much more efficient than the two methods based on simultaneous digonalization when $n \geq 10000$ and density = 0.01 and thus we also do not report the numerical comparison in this paper. We believe this is mainly because the simultaneously digonalization procedure of the matrices involves matrix inverse, matrix matrix product, a full Cholesky decomposition and a spectral decomposition (of a dense matrix), which is more time consuming than the operations of matrix vector products in our algorithm. Hence we do not report the numerical results based on the simultaneous digonalization technique.

5 Concluding remarks

In this paper, we have derived a simple convex quadratic reformulation for the GTRS, which only involves a linear objective function and two convex quadratic constraints under mild assumptions. We further reformulate the CQR to an unconstrained minimax problem under Condition 2.6, which is the case of interest. The minimax reformulation is a well structured convex, albeit non-smooth, problem. By

investigating its inherent structure, we have proposed two efficient matrix-free algorithms to solve this minimax reformulation. Moreover, we have offered a theoretical guarantee of global sublinear convergence rate for both algorithms and demonstrate a local linear convergence rate for Algorithm 1 by proving the KL property for the minimax problem with an exponent of $1/2$ under some mild conditions. Our numerical results have demonstrated clearly out-performance of our algorithms over the state-of-the-art algorithm for the GTRS.

As for our future research, we would like to show whether the CQR and the minimax reformulation and the algorithms for the minimax problem can be extended to solve GTRS with additional linear constraints. As the numerical and the preliminary analytical observation in the numerical section indicates that our algorithms have similar performance to unconstrained quadratic minimization, i.e., both algorithms admit a locally linear convergence rate with the steepest descent method, we would like to generalize existing algorithms that are efficient in solving unconstrained quadratic minimization to solve our minimax reformulation, e.g., the conjugate gradient method or Nesterov's accelerated gradient descent algorithm. Another line of future research is to investigate whether our algorithm can be extended to general minimax problems with more (finite number of) functions. It is also interesting to verify whether the KL property still holds and whether the KL exponent is still $1/2$ when more functions are involved.

A Discussion of Assumption 2.3

Assume that Assumptions 2.1 and 2.2 hold. Define $\text{Range}(Q_1) + \text{Range}(Q_2)$ as the summation of two subspaces, i.e., $\text{Range}(Q_1) + \text{Range}(Q_2) = \{u + v : u \in \text{Range}(Q_1) \text{ and } v \in \text{Range}(Q_2)\}$. When Assumption 2.3 fails, we have either $\text{Null}(Q_1) \cap \text{Null}(Q_2) \neq \{0\}$ and $b_i \in \text{Range}(Q_1) + \text{Range}(Q_2)$, $i = 1, 2$, or $\text{Null}(Q_1) \cap \text{Null}(Q_2) \neq \{0\}$ and $b_i \notin \text{Range}(Q_1) + \text{Range}(Q_2)$, for some $i \in \{1, 2\}$. The former case can be reduced to a case that satisfies Assumption 2.3 using null space representation for $\begin{pmatrix} Q_1 \\ Q_2 \end{pmatrix} x = 0$. We next show that the latter case leads to the situation where problem (P) can be either solved analytically or unbounded from below. To see this, note that the system in Lemma 2.5 is equivalent to the existence of a $\lambda^* \in I_{PSD}$ such that $b_1 + \lambda^* b_2 \in \text{Range}(Q_1 + \lambda^* Q_2)$, which implies $(b_1 + \lambda^* b_2) \perp \bigcap_{i=1,2} \text{Null}(Q_i)$. And λ^* can be derived analytically by solving the univariable linear system $\mathcal{N}(b_1 + \lambda^* b_2) = 0$, where \mathcal{N} is a linear operator that projects a vector to the space of $\bigcap_{i=1,2} \text{Null}(Q_i)$. If the linear system $\mathcal{N}(b_1 + \lambda^* b_2) = 0$ has no solution, the system in Lemma 2.5 has no solution and hence problem (P) is unbounded from below. In summary, our assumption is made without loss of generality.

B Sion's Minimax Theorem [43]

Lemma B.1. *Let X be a compact convex subset of a finite-dimensional Euclidean space, Y be a convex subset of a finite-dimensional Euclidean space and f be a real valued function on $X \times Y$. If*

1. *$f(x, \cdot)$ is upper semicontinuous and quasiconcave on Y , $\forall x \in X$, and*
2. *$f(\cdot, y)$ is lower semicontinuous and quasiconvex on X , $\forall y \in Y$,*

then

$$\min_{x \in X} \max_{y \in Y} f(x, y) = \max_{y \in Y} \min_{x \in X} f(x, y).$$

When f is bilinear, which is the case we used in the proof of Theorem 3.1, the items 1 and 2 are satisfied in the above lemma.
